Abstract

Biochemical and biomechanical signals drive cardiac remodeling, resulting in altered heart physiology and the precursor for several cardiac diseases, the leading cause of death for most racial groups in the USA. Reversing cardiac remodeling requires medication and device-assisted treatment such as Cardiac Resynchronization Therapy (CRT), but current interventions produce highly variable responses from patient to patient. Mechanistic modeling and Machine learning (ML) approaches have the functionality to aid diagnosis and therapy selection using various input features. Moreover, 'Interpretable' machine learning methods have helped make machine learning models fairer and more suited for clinical application. The overarching objective of this doctoral work is to develop computational models that combine an extensive array of clinically measured biochemical and biomechanical variables to enable more accurate identification of heart failure patients prone to respond positively to therapeutic interventions. In the first aim, we built an ensemble ML classification algorithm using previously acquired data from the SMART-AV CRT clinical trial. Our classification algorithm incorporated 26 patient demographic and medical history variables, 12 biomarker variables, and 18 LV functional variables, yielding correct CRT response prediction in 71% of patients. In the second aim, we employed a machine learning-based method to infer the fibrosis-related gene regulatory network from RNA-seq data from the MAGNet cohort of heart failure patients. This network identified significant interactions between transcription factors and cell synthesis outputs related to cardiac fibrosis - a critical driver of heart failure. Novel filtering methods helped us prioritize the most critical regulatory interactions of mechanistic forward simulations. In the third aim, we developed a logic-based model for the mechanistic network of cardiac fibrosis, integrating the gene regulatory network derived from aim two into a previously constructed cardiac

fibrosis signaling network model. This integrated model implemented biochemical and biomechanical reactions as ordinary differential equations based on normalized Hill functions. The model elucidated the semi-quantitative behavior of cardiac fibrosis signaling complexity by capturing multi-pathway crosstalk and feedback loops. Perturbation analysis predicted the most critical nodes in the mechanistic model. Patient-specific simulations helped identify which biochemical species highly correlate with clinical measures of patient cardiac function.

Dedication

I want to dedicate this dissertation work to my father, who died from a sudden cardiac arrest on the first day of graduate school. His passion for education has brought me to this country for higher education and helped me find my passion for cardiovascular disease research. I also want to dedicate this to my mother, whose whole life has passed raising our six siblings. My dedication also includes my siblings, especially my elder brother, for his endless contributions to shaping our family's bright future.

My Ph.D. journey would not be possible without the support and encouragement of the love of my life, my wife, Nazneen Sultana. She believed me and supported my decision to move to Biomedical Data Science. Without her, this journey would be unthinkable. Finally, I want to dedicate this to my son, Ibrazul Haque. His presence around me was uplifting and helped me to stay spirited.

Acknowledgement

I sincerely thank my adviser, Dr. William J. Richardson, for allowing me to work in his system mechanobiology research group for my dissertation. His profound knowledge and expertise in cardiac mechanobiology helped me to ignite my passion for cardiovascular disease research. His nurturing guidance, patience, and compassion helped me become a proficient researcher and a compassionate individual. Dr. Richrdson introduced me to the field of interpretable white box mechanistic models alongside machine learning techniques. His expert advice propelled me through this academic journey. Next, I would like to thank my committee chair Dr. Nina C. Hubig, for her encouragement to incorporate interpretable machine-learning approaches into my dissertation. I am also thankful to Dr. Brian C. Dean for wholeheartedly accepting me into the Biomedical Data Science and Informatics (BDSI) Ph.D. program. His confidence in my capabilities is a consistent source of motivation. I am also indebted to Dr. Bethany J. Wolf for her invaluable contributions as a committee member and for offering insightful feedback on my research proposal. Finally, I am grateful to Dr. Awe J. Schoepf for sparing his precious time from a demanding schedule to serve on my committee.

I am also grateful to the members of the System Mechanobiology Lab: Brendyn Miller, Jonathan Heywood, and Drs. Jesse Rogers, Amir Yeganegi, Kelsey Watts, Sam Coeyman, and Jake Potter. Special thanks to Dr. Jesse Rogers and Dr. Kelsey Watts for their well-written codes that I also used in my projects. I am also thankful to my BDSI cohort, especially Drs. MinJae Woo and Paritra Mandal for their constant encouragement and lengthy discussions. Finally, I express my heartfelt gratitude to my family members, especially my wife, Nazneen Sultana, for providing me with unfailing support and continuous

encouragement throughout my research and writing process. This milestone would not have been possible without them.

Chapter 1

Literature Review

1.1 Hypertension, cardiac remodeling, risk factors, and guidelines

Hypertension is the marked increase in systolic and diastolic blood pressure from the normal level. We can classify this increase into different categories based on the measurements of systolic and diastolic pressure, which is applicable for all age groups. Hypertension for a prolonged time results in future health complications and vital organ failures such as heart, brain, kidney, and eyes [1]. According to World Health Organization (WHO), an estimated 1.28 billion adults aged 30-79 years have hypertension worldwide [2]. An estimated 46% of adults with hypertension are unaware of the presence of hypertension. Only 1 in 5 adults with hypertension have it under control. WHO targeted hypertension as the leading non-communicable disease to eradicate by 2030. Nearly half of the US adults (47%) have hypertension. Only 1 in 4 adults with hypertension have their condition under control [2]. About 34 million adults in the USA take hypertension medication. Hypertension is the contributing factor to nearly half a million death per year in the USA [3].

Several factors increase the susceptibility to develop hypertension [4]. The risk of hypertension increases in elderly, male, and black individuals more prone to die from hypertension [5]. Individuals' family history also has a role in hypertension susceptibility. The presence of co-morbidity in parents risks the offspring developing hypertension. Higher BMI, physical inactivity, and a sedentary lifestyle also play a contributing factor in hypertension. Dietary habits such as high sodium, sugar, and alcohol intake are also positively correlated with hypertension. Stress and certain kidney diseases also increase the

probability of dying from hypertension. According to the European Society of Hypertension guideline (ESC/ESH guidelines on arterial hypertension (management of), hypertension evaluation consists of four categories based on their systolic and diastolic blood pressure range: Normal, Elevated, Stage 1, and Stage 2 hypertension. Hypertension evaluation also considers the secondary analysis of biochemical panels such as fasting glucose, lipid panel, thyroid-stimulating hormone. Several other biomechanical assays used for the assessment include eGFR, electrocardiogram, urinalysis [6].

Cardiac remodeling is the biochemical and biomechanical manifestation of the heart that results in the heart's change in size, mass, geometry, and function [7]. Cardiac remodeling primarily focuses on the heart's left ventricle because this is responsible for pumping oxygenated blood throughout the body. Cardiac function follows the simple Laplace formula ($T = Pr/2h$), where T is LV wall stress, P is pressure, r is the radius of the ventricle, and h is the LV wall thickness [8]. Increased blood pressure increases the stress on the LV wall so LV wall thickens to offset this pressure and normalize wall stress. This thickening results in the development of hypertrophy. There are two types of LV hypertrophy: concentric and eccentric. When elevated blood pressure increases LV wall stress, LV walls thicken (h) to offset this and normalize the wall stress. This is known as concentric hypertrophy. Eccentric hypertrophy develops when high blood volume increases the radius (r) of the heart chamber (V). The structure of the left ventricle is not only affected by pressure or volume overloads. Several other factors such as ethnicity, gender, neurohormonal characteristics, environmental and genetic factors are also responsible and may have additive effects in the overload of the cardiac chambers. Underlying medical conditions such as diabetes and chronic kidney diseases are the two confounders of cardiac remodeling [9]. Cardiac remodeling is reversible by doing regular exercise and lifestyle

modification [10]. Some studies have shown a negative correlation between physical activity and cardiac hypertrophy development.

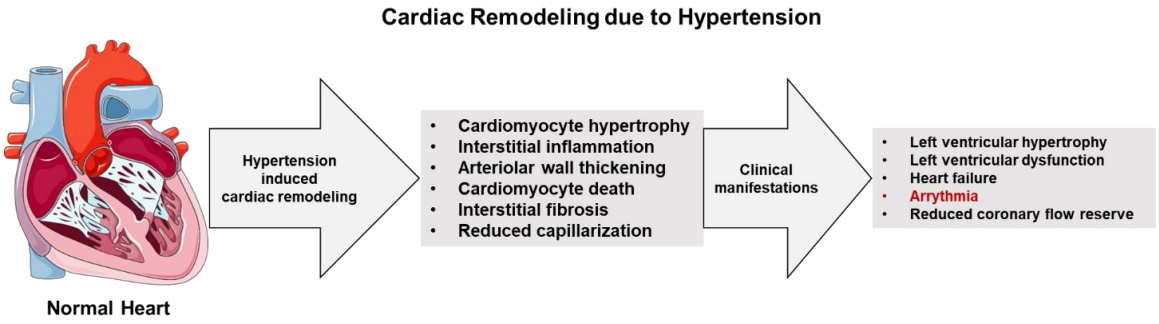

Figure 1.2. Cardiac remodeling due to hypertension and its clinical manifestation. Illustration modified from Servier medical art (https://smart.servier.com/) [9].

1.2 Biochemical markers for predicting cardiac remodeling

There are several vital biomarkers available for myocardial organ damage in hypertension [11]. Cardiac troponin is the first group of biomarkers that is part of the contractile apparatus of cardiac myocytes. Myocardial injury and cardiac remodeling increase the concentration of cardiac troponin [12]. The most common biomarkers for cardiac damage are C-reactive proteins (CRP) [13]. Many studies have shown that CRP concentration is associated with the increased risks of myocardial infarction and stroke. Mid-regional pro adrenomedullin (MR-proADM) is a peptide hormone generated by multiple tissues [14]. This hormone has a natriuretic, vasodilatory, and hypertensive effect. Soluble ST2 (sST2), a receptor for Interleukin 33 (IL-33), is also a prognostic marker for cardiac remodeling [15]. Several studies have shown that sST2 is associated with cardiac remodeling due to volume and pressure overload. The most common biomarker of cardiac damage is the low-density lipoprotein (LDL) [16]. Numerous studies have shown the positive correlation of LDL with increased atherosclerosis and cardiac remodeling [16]. Natriuretic peptides such as brain natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP) are also diagnostic biomarkers for cardiac dysfunction and remodeling [17]. Increased concentration of these peptides indicates higher ventricular wall stress, glomerular filtration rate, sodium and water extraction, and vasodilation. Another biomarker that also works as an indicator of cardiac and kidney damage is creatinine [18]. Copeptin is another biomarker responsible for the regulation of vascular tone and free water reabsorption [19]. Its lower level relates to cardiac remodeling with co-morbidity like diabetes mellitus.

In addition to circulating biomarkers for heart failure there are groups of biomarkers that actively participate in the cardiac remodeling process. Those molecules can be

separated into multiple groups such as C-terminal Propeptide of Procollagen Type I(PICP), Procollagen Type I N-terminal Propeptide (PINP); Procollagen Type III Amino-terminal Propeptide (PIINP), C-terminal Telopeptide of Collagen Type I (CITP), Matrix metalloproteinases (MMPs), Tissue inhibitors of metalloproteinase (TIMPs), Transforming growth factor-β (TGF-β), connective tissue growth factor (CTGF), endothelial to mesenchymal transition (EndoMT); Galectin-3 protein (Gal-3), tumor necrosis factor α (TNFα) [54]. These biomarkers are described in the later chapters in detail.

1.3 Predictive modeling for cardiac remodeling

Electrocardiogram (ECG) is the most common diagnostic tool to determine the biophysical profile of the heart. ECG is notorious for its low accuracy and sensitivity in diagnosing left ventricular hypertrophy [20]. Computational modeling and machine learning can help increase the predictive accuracy for left ventricular remodeling. Several studies have used machine learning techniques to improve the diagnostic capability to detect left ventricular remodeling. Fernando *et al*. used the C5.0 algorithm to improve the prediction of LVH [21]. Their resultant five-level binary decision tree used only six predictive variables and had an accuracy of 71.4% (95%CI, 65.5–80.2), a sensitivity of 79.6%, specificity of 53%. Another group compared different algorithms for predicting the LVH. They found the area under curves (AUC) for Logistic Regression (0.81), GLMNet (0.87), Random Forest (0.82), Gradient Boosting (0.80). Another interesting study has detected LVH using ECG signals based on machine learning techniques [22]. They used pathological attributes such as R wave, S wave, inversion of QRS complex, changes in ST-segment noticed in the ECG signal as their variables. After feature transformation, they have used the Support Vector Machine (SVM), K-Nearest Neighbor (KNN), Ensemble of Bagged Tree, AdaBoost

classifiers and compared them with four neural network classifiers including Multilayer Perceptron (MLP), Scaled Conjugate Gradient Backpropagation Neural Network (SCG NN), Levenberg–Marquardt Neural Network (LMNN) and Resilient Backpropagation Neural network (RPROP). They have found accuracy in detecting LVH is 86.6%, 84.4%, 93.3%,75.6%, 95.6%, 97.8%, 97.8%, 88.9% accordingly.

All the above and other models are not interpretable and therefore need improved interpretability. Moreover, none of these models were targeted toward the prediction of cardiac remodeling in hypertension. In addition, many research studies adopted interpretable machine learning models for hypertension [23]. They rely on easily explainable models such as linear and decision tree models [24]. The decision tree is easier to use for two reasons: Its simple representation of the complex model and readily identifiable features from the tree's top. Decomposing neural network into decision trees is another approach widely used by clinicians [25]. Some researchers also use a variant of traditional interpretable techniques to interpret their models. One such technique is Anchors [26], which is an extension of the common interpretable technique local interpretable model-agnostic explanations (LIME). Some rule extraction techniques are also used (MofN algorithm) [27], which tries to extract rules that explain single neurons by clustering the least significant neurons. Interpretation of the black box models is also used via visualization. Also, these visualization tools deal with only specific types of data (image, text, ECG data). However, this research used various types of data (ECG, Anthropomorphic, or Biophysical Data), very little information is available for their integration with biochemical data such as inflammatory mediators and RAAS fingerprinting [28]. This type of data should be a part of an interpretable machine model for cardiac remodeling.

1.4 Cardiac Resynchronization Therapy (CRT) and its benefit

The four chambers of our heart (two upper atrium and two lower ventricles) form two atrioventricular pairs consisting of one atrium and ventricle. Oxygen-depleted blood from the different parts of the body enters the heart by the right atrium and is pumped out by the right ventricle to the pulmonary artery to the lung and mixed with the oxygen. This oxygen-rich blood enters the heart again in the left atria, then to the left ventricle. Aorta then pumps out this blood to the body. This synchronous activity among four heart chambers results in the efficient pumping of oxygen-rich blood. When ventricles do not pump out the blood efficiently, it results in a dyssynchronous rhythm in the heart. As a result, arrhythmia symptoms start to appear. This Ventricular dyssynchrony is of three categories: Atrioventricular dyssynchrony, Interventricular dyssynchrony, and Intraventricular dyssynchrony [29]. Therapy aims to bring synchronization among heart chambers to manage heart failure signs. There are several methods of treating cardiac resynchronization such as medication, surgery, device-assisted ventricular functionality, heart transplant, lifestyle modification, and lifestyle management.

The most common procedure for treating the rhythm is cardiac resynchronization therapy (CRT). CRT works are performed by implanting a small device below the collar bone [30]. This device works as a pacemaker by monitoring the heart rate to detect abnormal heart rhythms and sending a small electric pulse to correct the pumping activity of the ventricles. As a result, the lower ventricles have better pumping ability and leak a lower amount of blood in the mitral valve. The muscle of the lower ventricles pumps better as a result of this coordination. CRT provides some advantages in patients with left ventricular dysfunction and prolonged QRS duration [31]. It reduces heart failure and hospitalization, and

prolonged survival compared with medical treatment such as medication. CRT is also valuable for patients to improve the symptoms and quality of life (QOL), increase exercise tolerance, and reduce the mechanical change in the left ventricle. Even though CRT provides many benefits, CRT fails for around 10-15% of the patients [32].

Patients who undergo CRT have two choices for devices [30]. They can opt for a Cardiac Resynchronization Therapy Pacemaker (CRT-P) or a Cardiac Resynchronization Therapy Defibrillator (CRT-D). The choice of treatment depends on the heart condition. If the heart is miserably failing, then the CRT-D is the only chance for cure [33]. In addition to pacemaker activity, CRT-D also serves as a defibrillator. This functionality is significant for patients who are at the advanced stage of arrhythmia.

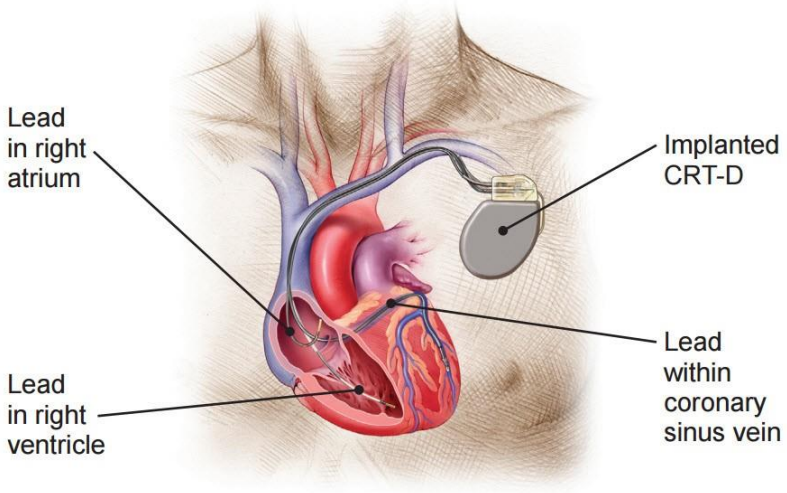

Figure 1.3. CRT-D Device. In addition to providing pacemaker activity, CRT-D provides defibrillation. It is taken from Boston scientific (https://www.bostonscientific.com/)

1.4.1 Role of biomarkers in the CRT response and cardiac remodeling

The American Heart Association and American College of Cardiology (AHA/ACC) 2008 and European Society of Cardiology (ESC) 2007 guidelines recommend some criteria such as patients with sinus rhythm, left ventricular ejection fraction ≤ 35%, QRS > 120ms, NYHA class III/IV [34]. Even after following all proper guidelines, almost one-third of the patients respond unfavorably to the treatment [35]. Biomarkers can help identify the patients who will better respond to the treatment [36]. Spinale and colleagues recently showed that specific serum protein biomarkers hold predictive power for CRT response. Expressly, elevated levels of a soluble suppressor of tumorgenicity-2 (sST-2), soluble tumor necrosis factor receptor-II (sTNFr-II), matrix metalloproteinases-2 (MMP-2), and C-reactive protein (CRP) indicated a reduced likelihood of benefit across 752 patients from the SMART-AV CRT trial. However, many recent clinical studies have tested the utility of advanced machine learning algorithms for predicting the response to CRT using various patient data, including electronic health records, clinical imaging, and others [36, 37-40]. These studies never showed the importance of using biomarkers in their models. Therefore, a biomarker scoring system is helpful in building predictive modeling for CRT response and cardiac remodeling. Thus, combining the biomarker-based matrices with various features from the SMART-AV trail clinical patient data is helpful in predicting response to CRT and cardiac remodeling.

1.4.2 Predictive Modeling for CRT Patient Selection

Machine learning can identify risks associated with a CRT implant and identify significant risks related to the treatment by finding essential variables. There are several studies have been conducted for algorithm-based CRT patient selection. The most recent

study included the use of electronic health record data to predict the outcome methods. They used gradient boosting algorithms to expect the response but ended up with a low recall value. Also, their study has lower accuracy (0.65) compared to other models to date [39]. The second study conducted by the Cleveland Clinic and John Hopkins University has shown that 690 and 253 patients have found AUC 0.72 for the Naïve Bayes Classifier. They have also seen a good result for logistic regression. They also used Adaptive Boosting but did not find satisfactory results like the first study [38]. The third study attempted to cluster the patients rather than predict the outcome of the treatment. They have used Multiple Kernel Learning for pressing the patients rather than classifying them [37]. Kalscheur et al. used the result of the COMPANION trial to predict the outcome of the treatment. They have found the best result using the Random Forest Algorithm (AUC 0.76) [40].

1.4.3 AV delay based clinical trials: SMART-AV clinical trial

The Atrioventricular (AV) node is situated at the center of the heart's electrical system and is responsible for transmitting the heart's electrical impulse from the atria to the ventricle. First, the Sinus (S) node generates an electrical signal that travels through the atria, resulting in the contraction/beat. Then these signals are collected by the AV node. After a brief delay, this signal passes through the ventricles. For normal heart function, there should be coordination between these two signals. For a healthy heart to work, we need a brief delay between these two signals. Without any coordination, ventricles may prematurely fill with blood from the atria and result in premature pumping. Disorder in the AV node results in the disruption of cardiac electrical signaling resulting in the fast and

slow pacing of the heart. These result in several symptoms due to the failure of the heart's electrical system.

The success of CRT treatment depends on the optimal atrioventricular (AV) delay. Therefore, CRT treatment requires import optimization of the AV node. Without proper optimization, CRT treatment can see 10-15% less efficiency [32]. The SMART-AV clinical trial uses three different algorithms to adjust the AV delay to synchronize the heart's electrical system. The outcome from the three different techniques did not vary significantly. The researcher hypothesized that systemic AV delay optimization with echocardiography and the SD algorithm is superior to a fixed nominal AV delay. This study showed that LV geometry improves after six months regardless of the AV delay method.

1.5 Interpretable Machine Learning

Machine learning interpretability entails the transparency and explainability of a machine learning model. Most machine learning models are not easily interpretable due to the complex internal mechanism of these models [41]. Application of machine Learning in large healthcare datasets requires understanding the variable interaction and how they interact with the labels or target. The lack of domain knowledge forces the modeler to emphasize more on accuracy than interpretability [42]. Complex black box models such as Support Vector Machines (SVM), Random Forest (RF), and Artificial Neural Networks (ANN) provide more accuracy but are not easy to interpret. Therefore, they are limited in the use of clinical decision making. General Data Protection Regulation (GDPR) by European Union (EU) is already limiting the use of Machine Learning in clinical decision-making. Model Explainability will be very important for popularizing their use in clinical interventions [43].

Table 1.1. Variable Measured in the SMART-AV Trial [31].

Domain	Individual Feature
Demographic (2)	Sex, Age
Physical Characteristics (5)	Height, Weight, Body Mass Index (BMI), Systolic blood pressure (BPSYS), Diastolic Blood Pressure (BPDIA), Pulse, Heart Rate at Rest (HRREST)
Co-Morbid Situation (6)	Paroxysmal Atrial Fibrillation (PAF), Renal Disease, Chronic Obstructive Pulmonary Disease (COPD), History of Left Bundle Branch Block (LBBB), History of Right Bundle Branch Block (RBBB), Ischemic Cardiomyopathy
Heart Failure (2)	QOL Score, 6 Minute Walk Distance
Surgical Interventions (3)	Sinoatrial (SA) Node Surgery, Coronary Artery Bypass Grafting (CABG), Pre-Cutaneous Coronary Intervention (PCI)
Medication (4)	Beta-Blocker (BB), Diuretics, Ace inhibitors or ARBs (ACE-ARB), Digoxin
Circulating Biomarkers (4)	Soluble Suppressor of Tumorgenicity-2(sST-2), Soluble Tumor Necrosis Factor Receptor-II (sTNFr-II), Matrix Metalloproteinases-2 (MMP-2), and C-Reactive Protein (CRP)
LV Assessment (7)	Left Ventricular End Diastolic Volume (LVEDV), Left Ventricular End Systolic Volume (LVESV), Left Ventricular Ejection Fraction (LVEF), Stroke Volume (SV), EDV/ESV, Cube Root
ECG (3)	AV Interval with Atrial Pacing, PR Interval with Atrial Pacing, QRS Width

1.6 Techniques used for interpreting machine learning models

Interpretable machine learning techniques are of two types: model-specific and model-agnostic. Model-specific specific interpretable techniques change the interpretability with the change of the model [44]. Model agnostic interpretability is not particular to any specific models. Therefore, these Explainability does not change with models. We can also explain the models on a global or local scale. Global model interpretability techniques show the response of individual features to the overall model outcome. Local model interpretation only deals with the small part of the model. For example, if we model the prediction of treatment, individual features have a specific weight toward the overall predictive outcome of the treatment. The importance of a particular variable varies for each of the patients. In the second case, the local interpretation is the way to explain the model. Local model interpretation is crucial for the precision medicine perspective. Table 4 represents some of the examples of interpretable techniques.

Table 1.2. Approaches of the interpretability models with examples [45].

	Global	**Local**
Model Specific	• Decision trees • Regression models • Naive Bayes classifier	• Set of rules (for a specific individual) • Decision trees (by tree -decomposition) • Most visual analytics-based • approaches • k-nearest neighbors

Model Agnostic	• Different variants of model compression/knowledge distillation/global surrogate models • Partial Dependence Plots (PDP), • Individual Conditional Expectation (ICE) plots • Black Box Explanations through Transparent approximations (BETA) (Lakkaraju) • Model Understanding through Subspace Explanations (MUSE) [46]	• Local interpretable model agnostic explanations (LIME) • Shapley additive explanations (SHAP) • Anchors • Attention map visualization, • Model Understanding through Subspace Explanations (MUSE)

All interpretable techniques are not great for their application in the field of clinical data science. The following table shows the advantage and disadvantages of using them in data science.

Table 1.3. Advantages and disadvantages of some common Explainability techniques [23]

Technique	**Advantage**	**Disadvantage**
Feature Importance	A highly compressed interpretation that considers the interaction between features	Unclear of usage in training or testing dataset

Partial Dependence Plot (PDP)	Clear interpretation	Assumption of independence between features
Individual Conditional Expectation (ICE)	Clear interpretation	Plots are overcrowded to understand
Feature Interaction	Detect all interactions been features	Computationally expensive
Global Surrogate Model	Easy to measure the goodness of the surrogate model using R^2	No clear-cut cutoff for R^2 makes trust issue of the surrogate model
Local Surrogate Model	A comprehensive explanation for different data types	Instable and close points have completely different explanations
Shapely Value Explanation	Based on Game Theory Theorem	Computationally very expensive

1.7 Logic-Based ODE Models in System Biology

Signaling pathways allow the cells to sense the sudden change in their surrounding environment. Cells respond by changing the transcriptional activity, metabolism, and other cellular activity inside the cell [47]. Signaling pathways are the interaction of several linear biochemical reactions. The combination of all these linear reactions makes signaling networks very complicated. Researchers have developed various cellular interaction network models. The two kinds of cellular interaction networks are abstract and dynamic models. Abstract or conceptual models only capture some static part of the cellular interaction [48].

Dynamic models discover the dynamics of the interaction of different reactions and pathways in the cell. Modeling biochemical interaction of the cell helps us to integrate the hypothetical and experimental results into a complete system. These systems are helpful to understand, support, or falsify the underlying mechanism of the cellular interaction network and understand the biological interaction at the system level.

Most of the cell signaling networks use standard cellular components. The most common element in the cellular signaling network is the receptor, which receives the extracellular stimuli from the outside environment. Some of these receptors are common across different eukaryotic cellular pathways. Therefore, the same receptor can be seen in various cellular networks. These interactions in different pathways inside of the cell finally end in producing or degrading specific proteins. The enzymes that catalyze these interactions are also produced by the intermediate proteins products in the cellular networks. For cardiac remodeling, most of the interacting proteins are either produced or degraded by specific gene-protein interaction networks. These receptors can switch from their active state to inactive states resulting is a biochemical reaction cascade inside the cell. The field of molecular biology consists of a vast amount of interaction data consisting of genomics, proteomics, metabolic, and immunological data. The main challenge of working with these data is finding interactions in these discrete data types [49]. Knowing the exact nature of these interactions is very important for the point of translation biology. Suppose anyone wants to design a drug targeting a specific component of the cell signaling network. While the drug might work on a particular target protein, they must know how this target protein interacts with all the parts of the cell signaling network. This knowledge of detailed interaction networks reduces off-target drug interaction. Therefore, abstract and dynamic models are both essential for capturing valuable information in the cell

signaling network. Structural or static networks correlate several pathways into an extensive network. Even though these networks are vast, they lack the directionality. Some of these static network only provides snapshot of the system at a specific point. An example of such a network is the gene co-expression network which only captures the gene expression pattern under a particular condition. They are not good at capturing the dynamic nature of any biological system [50].

Ordinary Differential Equations (ODE) are very good at capturing the dynamical characteristics of the biological system. Cellular interactions in such systems are a collection of chemical reactions and follow chemical rate laws. These laws represent better by the ODE. The only problem with the ODE model is that they have a vast parameter space. This parameter space is problematic for a large-scale network like biological systems. Therefore, a combination of such models is the logic-based ODE models. We do not need vast knowledge about the parameters for the logic-based ODE models. The only information we need here is the directionality. Therefore they are relatively easy to construct while they can easily catch the system wide response to perturbation [51].

The Hill equation is one of the most commonly used mathematical methods for studying enzyme reaction kinetics [52]. In biochemical interaction analysis, its primary use is for cooperative binding. The Hill equation describes the fraction of macromolecules saturated by ligand as a function of ligand concentration mathematically presented as-

$$\theta = \frac{[l]^n}{k_d + [l]^n} = \frac{[l]^n}{(k_a)^n + [l]^n} = \frac{1}{\left(\frac{k_a}{[l]}\right)^n + 1}$$

In this equation, θ is the fraction of occupied sites where the ligand can bind to the active site of the receptor protein. *[l]* is the free(unbound) ligand concentration, k_d is the apparent dissociation constant derived from the law of mass action, k_a is the ligand concentration producing half occupation, and n is the Hill Coefficient. When n>1, the cooperative binding is positive. If n<1, the cooperative binding is negative, and n=1 indicates no cooperative binding. For any biochemical species $x \in [0, 1]$, activation of *x*, *F(x)* modeled as normalized Hill function of the following form:

$F(x) = \frac{Bx^n}{k^n + x^n}$ with $B = \frac{EC_{50}^n - 1}{2EC_{50}^n - 1}$ and $k = (B-1)^{1/n}$

In this equation, *n* is the Hill Coefficient related to the curve's steepness, *and* EC_{50} is the enzyme concentration at which half-maximal activation occurs. Standard logic gate functions capture reaction interactions:

X AND Y = F(X)F(Y),

X OR Y = F(X) + F(Y) – F(X)F(Y),

X AND NOT Y = F(X)(1-F(Y))

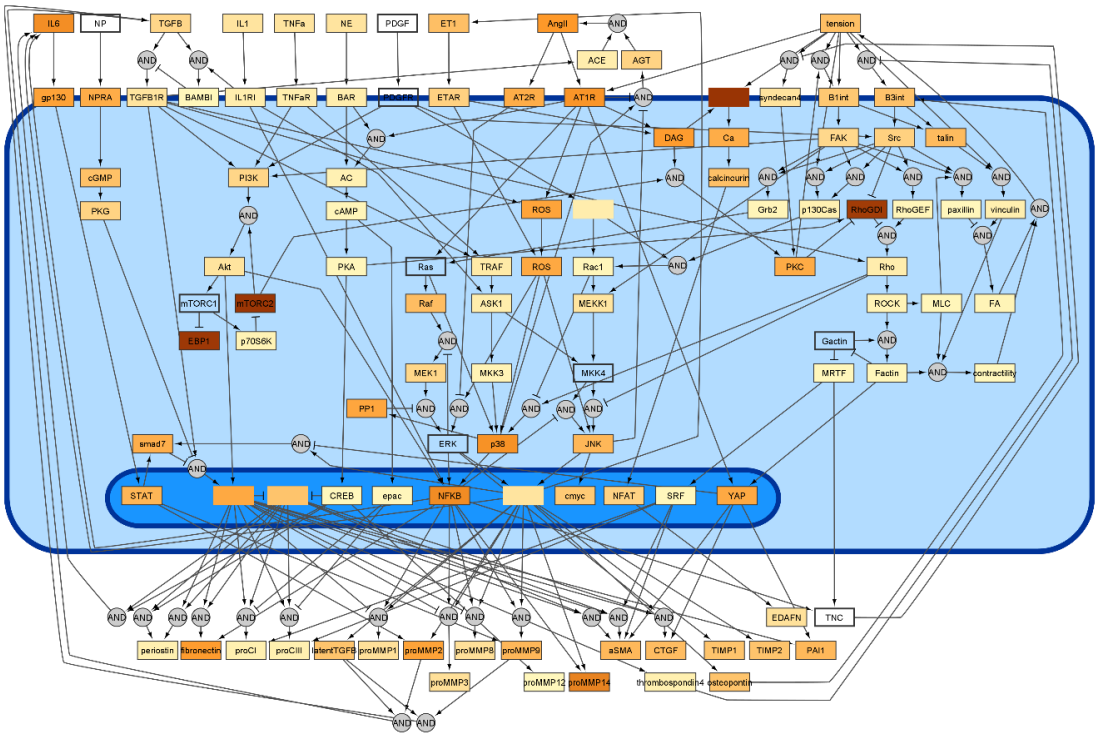

Figure 1.4. Fibroblast mechanotransduction network constructed using the logic-based ODE models.

Our lab has expertise in building cardiac cell signaling networks by manually curating biochemical transduction pathways from existing literature searches and their experimental validation (Figure 1.4). A study by Rogers et al. [53] has expanded a fibroblast mechano-chemo signal transduction capable of accurately predicting fibrosis-related protein expression in response to biochemical and biophysical force. They have shown the biochemical dose-response behavior under varying levels of mechanical stimulation. Their comprehensive model simulations of fibroblast responses to drugs in low- or high-tension contexts and identified several drug combinations that adapted fibrotic activity to the local mechanical state.

In this dissertation I will conduct the following research: In Aim 1, we will build an interpretable ML model for CRT response using biomarker and biomechanical features. We will build interpretable ML models using blood derived biochemical markers plus echocardiography-derived biomechanical features. These features will help us identify the patients who respond positively to CRT treatment before implanting the CRT device. Also, our model will show patient-specific features and how these features contribute to CRT. In aim 2, we will infer a gene regulatory network using the novel inference algorithm and filter them in the context of fibrosis to build a dilated cardiomyopathy specific network. We will use RNAseq data from Myocardial Applied Genomic Network (MGNet) study for this. In aim 3, we will developed a logic-based model for the mechanistic network of cardiac fibrosis integrating the gene regulatory network derived from aim 2 into a previously constructed cardiac fibrosis signaling network model. This integrated model implemented biochemical and biomechanical reactions as ordinary differential equations based on normalized Hill functions. The model elucidated the semi-quantitative behavior of cardiac fibrosis signaling complexity by capturing multi-pathway crosstalk and feedback loops. Perturbation analysis predicted the most important nodes in the mechanistic model and patient-specific simulations helped identify which molecules are most highly correlated with clinical measures of patient cardiac function.

Chapter 2

Interpretable machine learning predicts cardiac resynchronization therapy responses from personalized biochemical and biomechanical features

2.1 Introduction

Cardiac resynchronization therapy (CRT) is the preferred treatment method for patients with ventricular desynchrony accompanied by reduced ejection fraction and bundle branch block [1]. CRT reduces the risk of sudden heart failure due to the weakening of the heart muscle and canhelp alleviate the symptoms of heart failure and improve the quality of life [2]. The American Heart Association and American College of Cardiology (AHA/ACC) 2008 and European Society of Cardiology (ESC) 2007 guidelines recommend the following criteria for selecting patients for CRT: patients with sinus rhythm, left ventricular ejection fraction ≤ 35%, QRS > 120ms, NYHA class III/IV [3]. Unfortunately, roughly one-third of CRT recipients do not respond favorably to the treatment [4]. Given its expense and surgical risks, the ability to accurately predict individual patientbenefits from this treatment could hold great clinical value [5].

Spinale and colleagues recently showed that specific serum protein biomarkers hold predictive power for CRT response [6]. Notably, elevated levels of the soluble suppressor of tumorgenicity-2 (sST-2), soluble tumor necrosis factor receptor-II (sTNFr-II), matrix metalloproteinases-2 (MMP-2), and C-reactive protein (CRP) indicated a reduced likelihood of benefit across ~800 patients from the SMART-AV CRT trial. Other recent

studies have tested theutility of advanced machine learning algorithms for predicting the response to CRT using variouspatient data, including electronic health records, clinical imaging, and others [7–11]. These studies have shown modest predictive capabilities but have primarily utilized data types that largely ignored biochemical features such as serum biomarkers.

Most machine learning models are not easily interpretable due to their complex black-box nature for clinical decision-making [12-13]. A fair application of machine learning models in clinical datasets requires understanding the interaction of features with each other and target variables. Complex black box models such as Support Vector Machines (SVM), Random Forest (RF), and Artificial Neural Networks (ANN) though provide more accuracy but are not easy to interpret [14]. Therefore, they are limited in the use of clinical decision making. General Data Protection Regulation (GDPR) by European Union (EU) is already restricting machine learning in clinical decision-making [15]. Model interpretability is very important in clinical data science and should be part of clinical decision-making. Interpretable machine learning techniques are of two types: model-specific and model-agnostic [16]. Model-specific specific interpretable methods change the interpretability with the change of the model. Model agnostic interpretability is not particular to any specific models [17]. Therefore, these explainabilities do not change with a new model. We can also interpret machine learning models on a global or local scale. Global model interpretability techniques show the response of individual features to the overall model outcome. Local model interpretation only deals with a small part of the model. We have used model agnostic Global method SHapley Additive exPlanations (SHAP) [19] and Partial Dependence Plots (PDP) [20] for this study. We also used Local Interpretable Model agnostic Explanations (LIME) methods [21] for exploring the model locally.

In this study, we sought to computationally predict and interpret the patient response to CRT using a combination of demographics, physical characteristics, co-morbidities, medication history, circulating biomarker levels, and echo-based LV assessment. Building upon the previous work ofSpinale et al., we combined their biomarker-based metric with various features from the SMART-AV clinical patient data [23]. We assessed the performance of our resulting ensemble machine learning classification model using receiver-operating curve analysis for a hold-out patient dataset and comparisons of 6-month cardiac measures between model-predicted responder and non-responder groups. We also performed SHapley Additive exPlanations (SHAP) analysis to help interpret the global importance of all features included in the model. We also demonstrated how the top three features affect the overall model outcome. Finally, we have shown the top 10 features for two CRT recipients and how these ten features determine their response to CRT.

2.2 Methods

2.2.1 Study Population and Data Preparation

The data source for our model training and testing was the SMART-AV trial published previously [22]. In that study, 794 patients with NYHA class II and IV, LVEF ≤ 35%, and QRS duration ≥ 120 milliseconds were randomly assigned to different defibrillation protocols and evaluated at 0, 3, and 6 months with echocardiography and serum biomarker panels. The complete list of recorded features is organized in Table 1. A positive CRT response was defined as a decrease in ESV of at least 15 mL between 0 to 6 months post-surgery [23], and the patient cohort held a nearly equal split of responders (n = 396) and non-responders (n=398).

Patients with missing data were imputed using two different methods for our study. Surgical intervention features, PCI and CABG, were imputed to match the most frequent value for each of those features. Categorical data were transformed using one-hot encoding. Non-categorical data/continuous data were mean imputed, followed by the scaling using the StandardScaler methods [23]. The patients were split into training and testing datasets, with 80%in the training dataset (n=635) and 20% in the testing dataset (n=159).

In addition to feature imputation and scaling, continuous variables were compared between CRT responders vs. non-responders using the t-test. The mean and the standard deviation are reported with respective p-values. Categorical variables were compared using the chi-square test. The result from the statistical analysis is presented in Table 2.

2.2.2 Machine Learning Model Development

Using Python 3.6.4 and scikit-learn 0.23.2, we tested a wide variety of supervised classification machine learning algorithms, including K-Nearest Neighbors, Support Vector Classifier,Decision Tree Classifier, Random Forest, Adaptive Boosting, Gradient Boosted Classifier, Gaussian Naive Bayes classifier, Linear Discriminant Analysis, XGBoost, Catboost, Logistic regression, and Multi-Layer Perceptron Neural Network [24]. In addition, we tested Stacked and Voting ensembles with the training dataset [25-27]. Each model was tuned using a cross-validated grid search across hyperparameters with parameters selected to maximize the area under the receiver-operating characteristic curve (AUC) for binary classification of patients in thetraining set. Notably, the algorithm only used 0-month (pre-surgery) feature data to predict the 6-month post-surgery response vs. non-response outcome. Model performance was evaluated using 5-fold cross-validation, and the final model was selected based on the highest mean AUC. We have only presented the

performance of the top 6 models in Table 3. We have also demonstrated the overall model-predicted response rate for CRT responders vs. non-responders and stratified them based on the model-predicted responses probability score. We have also shown how the changes in secondary variables are related to the model-predicted response.

Feature selection was performed using a backward stepwise methodology, eliminating features that did not improve the model training score. A guiding hypothesis for this work wasthat combining the previously identified serum biomarkers with demographic and echo-based features would improve predictive capability. To evaluate this hypothesis, we trained and tested our ensembled model using three different sets of features, including all features listed in Table 1, and (1) no biomarker values, (2) all 12 biomarker values, or (3) a biomarker score based on previousanalysis by Spinale et al. [6]. The biomarker score is calculated for each patient by counting how many of the four critical biomarker analytes exceed a risk threshold (MMP-2, sST-2, CRP, sTNFR-II). All these results are presented in Table 4.

2.2.3 Model Interpretation

We have used several interpretable techniques to describe our model. To help interpret global feature importance, we performed a SHapley Additive exPlanations (SHAP) analysis using the Python tool SHAP 0.37.0 KernelExplainer and KernelSHAP [19]. We have also shown the partial dependence plot [20] to present the effect of the top three features on the overall model. Finally, we picked two examples of CRT recipients to show how the model behaves locally for responders and non-responders. To show that local behavior, we have used the LIME tool to create the LIME graph [21].

2.3 Results

2.3.1 Model Predictive Performance

Across all the algorithms tested, a majority-voting ensemble classification model demonstrated the best performance. The ensemble consisted of nine equally weighted models, each voting with their respective probability of surgical success: a Linear Discriminant Analysis classifier, a Catboost Classifier, a Gradient Boosted classifier, a Random Forest classifier, an XGBoost classifier, a Support Vector Classifier, a 3-layer Multilevel Perceptron Neural Network, a Logistic Regression Classifier, and an Adaboost classifier. Without using biomarker data, our algorithm approach demonstrated modest predictive performance with an AUC of 0.63 in the training patient set (Table 3). The addition of biomarker data substantially improved model performance, with an AUC reaching 0.75 in the training patient set and almost 0.784 in the test patient set using either all 12 biomarkers or the simplified biomarker composite score (Table 2.1, Figure 1A). Using the biomarker score reached the highest AUC in both the training and test patient set, so we proceeded with the biomarker score model for the remaining analyses.

Our binary classification model correctly predicted 71% of patient responses in the test set, with 61/88 classified responders and 52/71 classified non-responders matching the trial result (Figure 2.1B). To analyze more detailed patient stratifications, we separated patients into five groups according to the model-predicted probability of response (i.e., p = 1-0.8, 0.8-0.6, 0.6-0.4, 0.4-0.2, or 0.2-0). Across the stratified patients, the model correctly identified 96% of patients in the highest and lowest response groups, with 14/15 patient responders in the high probability score group and 8/8 non-responders in the low probability score group (Figure 2.1B).

In addition to response rate (which is judged by a strict over/under -15mL threshold for ESV change over six months), we also explored quantitative changes in left ventricle remodeling metrics across the model classification groups (Figure 2.2). Over six months after the procedure, patients classified by the model as responders showed significant reductions in both ESV and EDV, while patients classified as non-responders showed no change in ESV and a slight increasein EDV over six months. Both responders and non-responders showed increased stroke volumes and ejection fractions, but the model-predicted responders showed a statistically more significant improvement in ejection fraction (~40% compared to ~20%). These discrepancies between groups were amplified further across the 5-group patient stratification using the model probability score (Figure 2.2B). In the most extreme case, the high response probability group exhibited almost a 75% improvement in ejection fraction, while the low response probability groupexhibited no change in ejection fraction over the 6 months after surgery.

2.3.2 Model Interpretability

To improve the interpretability of our ensemble classification algorithm, we performed a SHAP analysis and corresponding visualization of feature importance (Figure 2.3A). Briefly, this technique calculates a collective, global average of how much each feature value contributed to each patient's classification in order to indicate both magnitude and direction that each feature contributes to the overall probability of falling on either side of the binary classifier (i.e., respondersvs. non-responders). SHAP analysis indicated that, in general, lower 1D stretch, lower biomarkerscore, absence of ischemic cardiomyopathy, lower QOL score, and higher age were strong contributors within the algorithm for identifying responders. In Figure 2.3B, we have shown the partial dependence between

CRT response and the top three features from our fitted Majority Voting model: 1D stretch, Biomarker Score, and Ischemic Cardiomyopathy. From the topmost plot, we could see that the chance of responding to CRT significantly decreases with increasing 1D Stretch between 1.03 to 1.39. The biomarker score follows the same trend. Increased biomarker score results in lower response to CRT. Finally, the history of Ischemic Cardiomyopathy also decreases the chance of CRT response.

We also implemented our model locally using the LIME method. We have presented two local interpretations of our model. These interpretations demonstrated how patient-specific biomarkers vary for response vs. non-response to CRT. Figure 2.4A showed a patient with a higher probability of responding to CRT (0.81) and the top ten features contributing to that. For this patient, 1D Stretch of less than or equal to 1.08 and no history of RBBB, Atrial Flutter, Ischemic Cardiomyopathy, AT-PSVT, PAF, and SA are helping to move the patient to the response regimen. But No history of VT-SVT, Non-stained VT, and Biomarker Score of more than 2 contribute to non-responsiveness for this patient. Figure 2.4B showed a patient with a higher probability of non-responding to CRT (0.75) and the top ten features contributing to that. For this patient, a 1D Stretch of greater than 1.14, a history of Ischemic Cardiomyopathy, and no history of variables VT-SVT, Afib, and Nonsustained VT are helping to move the patient to the non-response group. But No history of RBBB, Atrial Flutter, SA surgery, PAF, and Biomarker Score of zero is responsible for a small probability of response in this patient.

2.4 Discussion

Machine learning has a trust issue in clinical decision-making due to the black-box nature of the machine learning algorithms [28]. Most sophisticated black-box algorithms

provide a higher accuracy but are impossible to interpret in terms of patient variables. On the other hand, the Glassbox machine learning model, such as linear regression, though very easy to interpret but comes with a risk of low model accuracy. We need to balance accuracy and interpretability to adopt machine learning for therapeutic decision-making like CRT [29]. Our majority voting algorithm has higher accuracy and covers a higher area under the curve (Figure 2.1, Table 2.3/2.4). Also, in this study, we used a biomarker scoring system to improve the predictive capability of our model. The only study that used biomarkers to predict CRT response was the COVERT-HF study [30]. Though they used a wide variety of biomarkers, our study showed that a biomarker scoring consisting of four biomarkers: MMP-2, sST-2, CRP, and sTNFR-II, is enough to build an interpretable model with high accuracy and AUC than using twelve biomarkers (Table 2.4).

While CRT offers significant clinical benefits for many heart failure patients, a large proportion of the population does not respond positively to treatment [4]. This high patient-to-patientvariability presents a need for predictive methods to help identify which patients will or will not benefit from CRT based on information obtained prior to the procedure. Several studies havedeveloped computational algorithms spanning black-box machine learning and sophisticated electromechanical finite element modeling to help predict CRT response based on varying information, including electronic health records, clinical imaging, demographic data, and more [7-11]. Some of the studies have had moderate predictive success, but most studies have generally focused their analyses on only one type of data source, and very little attention has been given to the predictive capability of circulating biomarker panels. We hypothesized thatintegrating multiple data sources and including biochemical levels from serum panels would significantly improve the predictive ability of machine learning algorithms. Using previously obtained patient data in the SMART-AV

trial, we built a novel algorithm that integrates demographic data, physical characteristics, medical history, circulating biomarkerlevels, and echocardiography data to improve the prediction of CRT response prior to surgical intervention. In a previous study, Spinale and colleagues showed significant predictive power foridentifying CRT response using pre-surgical levels of specific serum protein biomarkers (sST-2, sTNFr-II, MMP-2, and CRP)[6]. Given the crucial roles of inflammation and extracellular matrixturnover for regulating cardiac remodeling related to CRT, it should be no surprise that circulatingproteins are associated with CRT response either as upstream regulators or downstreamcorrelates. We combined the Spinale et al. patient biomarker score with 40 other input features spanning echo-based LV metrics, medical history, demographic information, and basic clinical assessments. Using these features enabled our ensemble machine learning classifier to correctlyidentify 71% of patient response outcomes, achieving an AUC of 0.784 – a substantial improvement over the previous study using the biomarker score alone.

A significant limitation of many machine learning approaches is their ‘black-box’ nature of predictions, or in other words, their un-explainability. Future adoption of artificial intelligence into the clinical decision-making process will undoubtedly be affected by an ability to explain (to somedegree at least) why models predict what they predict and to identify the driving variables within the algorithms, especially for high-risk and costly decisions like CRT treatment. In order to improve such interpretability, a growing emphasis is being put on ‘glass-box’ or ‘white-box’ techniques . We employed SHAP analysis to elucidate the relative contribution of each feature to the patient response probability output of our model (Figure 2.3). This analysis revealed that important featurescame from diverse data sources, with the top five features including echo-based data (1D stretch),serum protein data (biomarker score), co-morbidity data (ischemic cardiomyopathy), clinical

evaluation data (QOL score), and demographic data (patient age). In addition, LIME revealed features responsible for personalized prediction and showed diverse feature sets responsible for individual response to treatment. All of these interpretable techniques only provide a clear picture of the mechanistic insight of the model, not the causality [31]. Of course, we must emphasizethat the power of these features to predict CRT response is indicative of their correlation to cardiacremodeling and not necessarily indicative of their mechanistic causation of cardiac remodeling. Additional notable limitations include a relatively short follow-up time of 6 months and a relativelysmall patient sample size (compared to thousands of patients' data used in electronic health record-based algorithms).

Current clinical guidelines define specific eligibility criteria for physicians to base their CRT recommendations [32]. The increasing accuracy of computational predictions suggests that incorporating personalized model-based probabilities could benefit such recommendation criteria.Encouragingly, our patient stratification demonstrated 96% accuracy in the highest and lowest response subgroups with significant differences in volume changes and functional changes over six months post-CRT. Our algorithm was built and tested using only baseline, pre-CRT measurements, demonstrating that it is feasible for machine learning algorithms to harness a composite set of data from the demographic, functional, and biomarker domains obtained at the time of patient evaluation for CRT and provide predictive value on the ultimate CRT response. As future model developments are likely to further improve prediction accuracy across a broader number of patients, future clinical and ethical discussions will prove vital to appropriately leveragethis predictive information into CRT decisions.

2.5 Conclusion

In this study, we have shown that integrating multiple types of data and biomarkers scoring improves the predictive capability of machine learning algorithms to identify CRT responders and non-responders. Our ensemble model combining all data types has better predictive power than only using cardiac functional markers. We have also shown the Global & Local Explainability of our ML model in terms of overall and personalized prediction. These explainabilities will be helpful to understand the response to the treatment in depth. They will help understand the nature of response for individual CRT recipients. Therefore, this research perfectly aligns with the goal of personalized precision medicine in cardiovascular diseases.

2.6 Acknowledgments

We gratefully acknowledge Doug Stubbs, Dr. Nina Hubig, and Dr. Frank Spinale (USC School of Medicine) for their collaboration on this chapter.

2.8 Figures Legends

Figure 2.1. Overall performance of the machine learning model.

The receiver-Operating Characteristic curve for the supervised, binary classification ensemble model demonstrates high predictive capability with an area-under-the-curve of 0.784 for the majority voting classifier. (B) Model-predictedresponders exhibited a 69% response rate (61/88), while model-predicted non-responders exhibited only a 27% response rate (19/71). Further stratification based on the model-predicted responses probability score demonstrated a greater predictive accuracy.

Figure 2.2. Cardiac remodeling across patient stratifications.

Model-predicted responders showed statistically significant differences in left ventricle remodelingmetrics compared to the model-predicted non-responders. In particular, binary classification (A) identified a responder group with substantially greater improvements in ESV, EDV and EF from 0-6 months after CRT intervention. (B) More detailed patient stratification further amplified the remodeling differences across groups.

Figure 2.3. SHAP plot and PDP plot showing the feature importance and marginal effect of one feature at a time in the prediction model. (A) SHAP plot showing the feature importance in our model. 1D stretch, biomarker score, ischemic cardiomyopathy, QOL score, and age were indicated as the top 5 most important features for determining patient response probability. The scatter width and separation indicate the feature importance, and the color indicates which direction of that feature value is predictive of high

vs. low patient response. (B) An increase in 1D Stretch from (1.03 to 1.39), Biomarker Score, and History of Ischemic Cardiomyopathy increases the risk of not responding to CRT.

Figure 2.4. LIME plot showing local approximation and interpreting the model locally for two patients; responder vs non-responder. LIME plot is also explaining how top 10 features contributing for individualized response to CRT. (A) 1D Stretch of ≤ 1.08, and no history of RBBB, Atrial Flutter, Ischemic Cardiomyopathy, AT_PSVT, PAF, and SA surgery increased probability of responding favorably to CRT treatment. (B) 1D Stretch of > 1.14 and no history of VT-SVT, Afib, and Non-sustained VT increased the probability of not responding to treatment. On the other hand, history of Ischemic Cardiomyopathy also greatly affecting the non-response to CRT.

2.9 Tables

Table 2.1. Variables acquired from the SMART-AV clinical trial.

Domain	Individual Feature
General Characteristics (9)	Sex, Age, Height, Weight, Systolic bloodpressure (BPsys), Diastolic Blood Pressure (BPdia), Heart Rate at Rest (HRrest), QOL Score, 6-Minute Walk Distance
Co-Morbidities (10)	Atrial Fibrillation (Afib), Paroxysmal Atrial Fibrillation (PAF), Atrial Flutter, Renal Disease,Chronic Obstructive Pulmonary Disease (COPD), Premature Ventricular Contractions (PVC), Atrial Tachycardia Paroxysmal Supraventricular Tachycardia (AT-PSVT), History of Left Bundle Branch Block (LBBB), History of Right Bundle Branch Block (RBBB), Ischemic Cardiomyopathy
Surgical History (3)	Sinoatrial (SA) Node Surgery, Coronary Artery Bypass Graft (CABG), Pre-Cutaneous Coronary Intervention (PCI)
Medications (3)	Diuretics, Ace inhibitors, or ARBs (ACE-ARB), Digoxin
Echo-based Assessment (7)	Left Ventricular End Diastolic Volume (LVEDV), Left Ventricular End Systolic Volume (LVESV), Left Ventricular Ejection Fraction (LVEF), Stroke Volume (SV), EDV/ESV, 1-Dimensional Stretch (cube root of EDV/ESV), Center size
ECG (12)	AV Interval without Atrial Pacing, PR Interval without Atrial Pacing, QRSWidth, VT None, VT Non-sustained, VT Supraventricular

	Tachycardia (VT-SVT), Sick Sinus, Paced AV Delay, Echo Optimized AV Delay, Iterative AVDelay, Fixed AV Delay, Sensed AV Delay
Biomarker	Matrix Metalloproteinase 2 (MMP-2), Matrix Metalloproteinase 9 (MMP9), Suppression of Tumorigenicity 2 (sST-2), C-ReactiveProtein (CRP), N-terminal pro B-type Natriuretic Peptide (NT- proBNP), Tissue Inhibitors of Metalloproteinase 1 (TIMP1), Tissue Inhibitors of Metallo-proteinase 2 (TIMP2), Tissue Inhibitors of Metalloproteinase 4 (TIMP4), Soluble Glycoprotein 130 (sGP130), Soluble Interleukin 2 Receptor Al-pha (sIL2Ra), Tumor Necrosis Factor Receptor II (sTNFR-II), Interferon Gamma (IFNg)

*** All the Biomarkers were used for creating the initial model. MMP-2, sST-2, CRP, and sTNFR-II are used for Biomarker Scoring.

Chapter 3

Building a Fibrosis Related Gene Regulatory Network in Dilated Cardiomyopathy Patients

3.1 Introduction

Cardiomyopathies are pathologies of cardiac muscle that result in the change of the mechanical and electrical disruption of the heart [1]. Cardiomyopathies have several phenotypes, such as Hypertrophic (HCM), Dilated (DCM), Peripartum (PPCM), and Restrictive Cardiomyopathy [2]. Some types of cardiomyopathies are common in young adults (DCM), while some types of cardiomyopathies may result from physical change due to age (restrictive) or pregnancy (PPCM). Dilated cardiomyopathy is non-ischemic cardiomyopathy that may result in ventricular dysfunction even without risk factors such as coronary artery disease, valvular disease, or congenital disorders. According to American Heart Association definitions, DCM can be hereditary and nonhereditary. Genetic cardiomyopathy involves the mutation of genes vital for cardiac functions. Nonhereditary dilated cardiomyopathy results from bacterial infection, protozoal infection, viral infections, autoimmune reactions, toxin exposure, and adverse neuromuscular changes. Dilated cardiomyopathy sometimes results in no symptoms, especially in the early stage of the disease. As the symptoms progress, cardiomyopathy patients feel fatigued, have shortness of breath during physical activity or while lying down, reduced ability to exercise, swelling (edema) in the legs, feet, and abdomen, discomfort in the chest, and rapid palpitations. Globally the incidence of cardiomyopathy has not drastically decreased even with

improved treatment and disease management [3]. According to a CDC study, 1 in 500 adults have cardiomyopathy-related conditions [4].

In the USA, several studies have attempted to identify risk factors for cardiovascular diseases. Some of these studies have been incredibly successful and have contributed to our predictive knowledge of cardiovascular disease [5]. One study, the Myocardial Applied Genomic Network (MAGNet) [7], collected extensive data from the left ventricle of DCM patient. The data of this study has been widely used to investigate the population genetics of DCM. Our study is unique in terms of its goal. While other studies aim to investigate the differential gene expression in dilated cardiomyopathy compared to non-failing patients, our goal is to identify the fibrotic factors involved in dilated cardiomyopathy.

A large part of dilated cardiomyopathy involves hereditary changes [8]. Therefore, it is important to understand the genetic landscape of cardiac myopathy. Several genes are involved in dilated cardiomyopathy phenotypes. The main genetic factors of dilated cardiomyopathy are Titin (TTN), Lamin A/C (LMNA), Myosin heavy chain (MYH7), Myosin binding protein C (MYBPC3), Myopalladin (MYPN), Sodium Channel alpha unit (SCN5A), BaCl2-associated Athano Gene 3 (BAG3), and Phospholamban (PLN). While they are important biomarkers for DCM, little efforts have been made to integrate these markers in a multipath way network of interactions to mechanistically understand their role in cardiac remodeling.

Myocardial fibrosis, which is defined as the deposition of extracellular matrix in the heart, is an important remodeling process and is intrinsically involved with cardiomyopathy phenotypes [9]. Therefore, it is important to study cardiomyopathy in the context of fibrosis. The very first step is to understand the genomic signature/hallmark signature of cardiac

fibrosis to find a link between the genetic signature of DCM and fibrosis. Gene regulatory networks are collections of different molecules within cells that work together to activate specific target molecules, leading to specific phenotypes. These molecules include DNA, RNA, and proteins [10]. Transcription factors (TFs) and their target relationships are important components of gene regulatory networks. Differential gene regulatory networks activate different cellular responses by activating different genes and transcription factors in the gene regulatory networks. Therefore, specific disease phenotypes have their own network of transcription factors (TFs). In this study, we are studying such networks in the context of cardiac fibrosis in dilated cardiomyopathy patients.

This chapter has these purposes: identifying important genetic modules that differ between non-failure controls (NF) and DCM patients, identifying pathways that are involved in this differential expression and finally identifying the transcription factors that paly major role in cardiac fibrosis in DCM patients. The purpose of the study is depicted in Figure 3.1. The first step involves differential expression analysis, followed by gene set enrichment analysis and weighted gene co-expression analysis. This is followed by inferring a large subnetwork in the upregulated and downregulated genes in the differentially expressed gene analysis. For the second part, we have built a transcription factor and target network and subsequently filtered it to identify the TF factors and targets responsible for causing fibrosis in DCM patients. These filtered transcription factors will be used subsequently to build the composite network in aim 3.

3.2 Materials and Methods

3.2.1 Data Source

The study was conducted using the Myocardial Applied Genomic Network Study (MAGNet) data source. MAGNet aimed to collect human left ventricle tissues for research purposes. The left ventricular free-wall tissue was collected from cardiomyopathy patients during cardiac surgery for heart transplant. For non-failing controls, samples were collected from unused donor hearts with normal functions [4]. RNA-Sequencing libraries were prepared against the hg19/hGRC37 using the STAR aligner. The RNA-seq data from this study has been stored in the NCBI GEO database (GSE141910). Two sets of data were utilized for this study. Raw read counts from the study were used for differential expression analysis, and these counts were obtained from the study's GitHub page (https://github.com/mpmorley/MAGNet). To identify important transcription factors, Surrogate Variable Analysis (SVA) normalized data from the same GitHub repository was retrieved [13]. The dataset consisted of 166 non-failing samples and 166 DCM samples.

3.2.2 Identification of the Differentially Expressed Genes

For the differential expression analysis, functional enrichment, and GO analysis, we utilized the integrated Differential Expression and Pathway analysis (iDEP) web application [11]. This web application comprises 63 R/Bioconductor packages, 2 web services, and is connected to several data repositories containing 220 plant and animal species. Since the raw data included numerous zero Counts Per Million Values (CPM) rows, we filtered the dataset for a minimum CPM of 1 and presence in at least 2 libraries. For clustering and Principal Component Analysis (PCA), we transformed the data using the EdgeR log2(CPM+c) transformation [12]. Missing values were imputed using the median method

to replace the missing CPM values. To cluster the gene expression data, we employed the elbow method to determine the optimal number of clusters. For the differential expression analysis, we utilized the limma-voom transformation method to analyze the data. We only considered genes whose log2 fold change was at least 2-fold. Due to the large sample size, we could not use the DESeq2 method. Furthermore, we performed enrichment analysis on the differentially expressed genes, both upregulated and downregulated, using the GO biological process for pathway enrichment.

3.2.3 Functional Enrichment Analysis

We utilized the Generally Applicable Gene-set/Pathway Analysis (GAGE) for pathway enrichment analysis [14]. A pathway significance cutoff (FDR) of 0.4 was applied, and the top pathways were identified. Additionally, we identified the significant KEGG pathways that were upregulated in the differentially expressed genes.

3.2.4 Weighted Gene CO-expression analysis

We also used the identified the weighted gene expression network WGCNA package [15]. We have only included the genes that are differentially expressed and shared among pathways between the Non Failing and DCM patients.

3.2.5 Target Gene-TF regulatory network analysis

3.2.5.1 Gene Regulatory Network Inference

We applied the method described by Rogers et al. [16] to derive the TF-target gene regulatory network using the dataset derived from the MAGNet study. To maintain the reproducibility of the study, we used the dataset from the MAGNet study to infer the gene regulatory network. To normalize the expression levels of the dataset, we employed the

counts per million (CPM) method and then transformed the data using the VOOM procedure in the LIMMA R package. Surrogate Variables (SV), which account for latent sources of variation such as batch effects, were calculated using the svaseq function from the R SVA package [13]. Differential gene expression analysis between races was performed using the LIMMA R package. We used a linear model with the following form: $Y = \beta0 + \beta1 \times race + \beta2 \times sex + \beta3 \times Age + \beta4\text{-}14 \times SVA1{:}SVA11$. In this model, Y represents the log2-transformed gene expression, and race is either African Americans or European Americans. We adjusted for gender, age, and 11 other surrogate variables, including etiology, weight, height, heart weight (hw), size of left ventricular mass, atrial fibrillation, presence of ventricular fibrillation/ventricular flutter, diabetes, hypertension, Left Ventricular Ejection Fraction (LVEF), RNA integrity number (RIN), and Transcript Integrity Number (TIN).

For the gene regulatory network analysis, we implemented the GRNBoost2 algorithm using the Arboretto library in Python [17]. The GRNBoost2 method is based on the GENIE3 algorithm [18], which predicts regulatory links between input and target genes using a decision tree ensemble method. The expression of a group of input genes is used to predict the expression of a target gene through the decision tree ensemble method. We chose the GENIE3 algorithm for several reasons [19]: it is widely used as a standard gene regulatory network inference algorithm, requires minimal assumptions about the network topology, provides directed interactions, and can infer nonlinear and combinatorial regulation compared to other regression-based methods.

Overall, we used the method by Rogers et al. to construct the TF-target gene regulatory network using the MAGNet study dataset. We performed preprocessing steps, conducted differential gene expression analysis, and employed the GRNBoost2 algorithm

based on the GENIE3 algorithm for network inference, taking advantage of its ability to infer regulatory interactions in gene networks.

3.2.5.2 Network Pruning

The initial network consisted of multiple interactions that may or may not be relevant to the context of cardiac fibrosis. To fit the network to our specific context and dataset, we applied three filtering steps, similar to Rogers et al.'s approach. In the first filtering step, we only selected interactions that are experimentally validated and involve transcription factors. This ensures that our network includes only reliable interactions supported by experimental evidence. In the second step, we focused on transcription factors that have evidence-based connections with mediators of cardiac fibrosis. This step helps refine the network by prioritizing transcription factors directly associated with the pathways involved in cardiac fibrosis. In the third filtering step, we retained only the interactions that were ranked highly by the GRNBoost2 algorithm. GRNBoost2 is used to predict regulatory links, and by selecting high-ranking interactions, we aim to prioritize the most influential and significant connections in the network.

For the first pruning step, we specifically chose transcription factors that have been validated in the CHIPX and TRANSFAC databases [20]. Transcription factors not found in these databases are not considered regulatory elements for our network. In the second step, we selected transcription factors that are connected to proteins involved in the extracellular matrix (ECM) turnover, ECM organization, and acute immune responses during cardiac fibrosis. This additional criterion ensures that the network is centered with transcription factors relevant to cardiac fibrosis. In addition, we added top genes that are differentially expressed in NF vs DCM patients (MYH6, COL22A1, COL10A1)

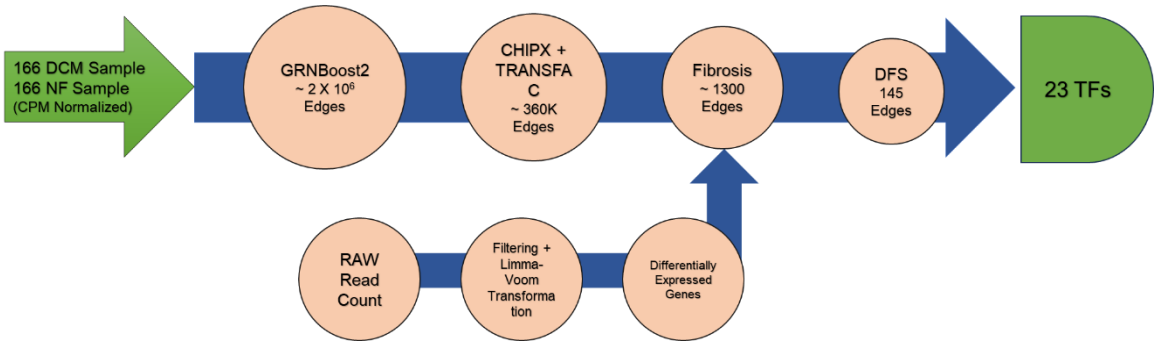

Figure 3.1. Differential gene expression analysis and integration of the DEGs into Gene Regulatory Network to build DCM related network.

3.3 Results

3.3.1 Differentially expressed genes in Normal vs Dilated Cardiomyopathy Patients

After preprocessing and filtering the data to ensure a minimum of 1 Count Per Million (CPM) read in at least 2 libraries, we obtained a total of 20,853 genes that passed the filter. To handle missing values, we employed the median-based imputation method. Following the imputation, we identified 870 genes that were significantly upregulated in the DCM tissue samples compared to the non-failing (NF) heart tissues, with a P-value < 0.05. In contrast, 358 genes were found to be downregulated in the DCM patients compared to NF samples.

We visualized the log2 fold change of all the genes in the volcano plot, where the grey area represents genes with no significant change in expression (neither up nor downregulated). The left blue region corresponds to downregulated genes, while the right red region indicates upregulated genes. Additionally, we presented a scatter plot illustrating the expression levels of the genes across all the samples.

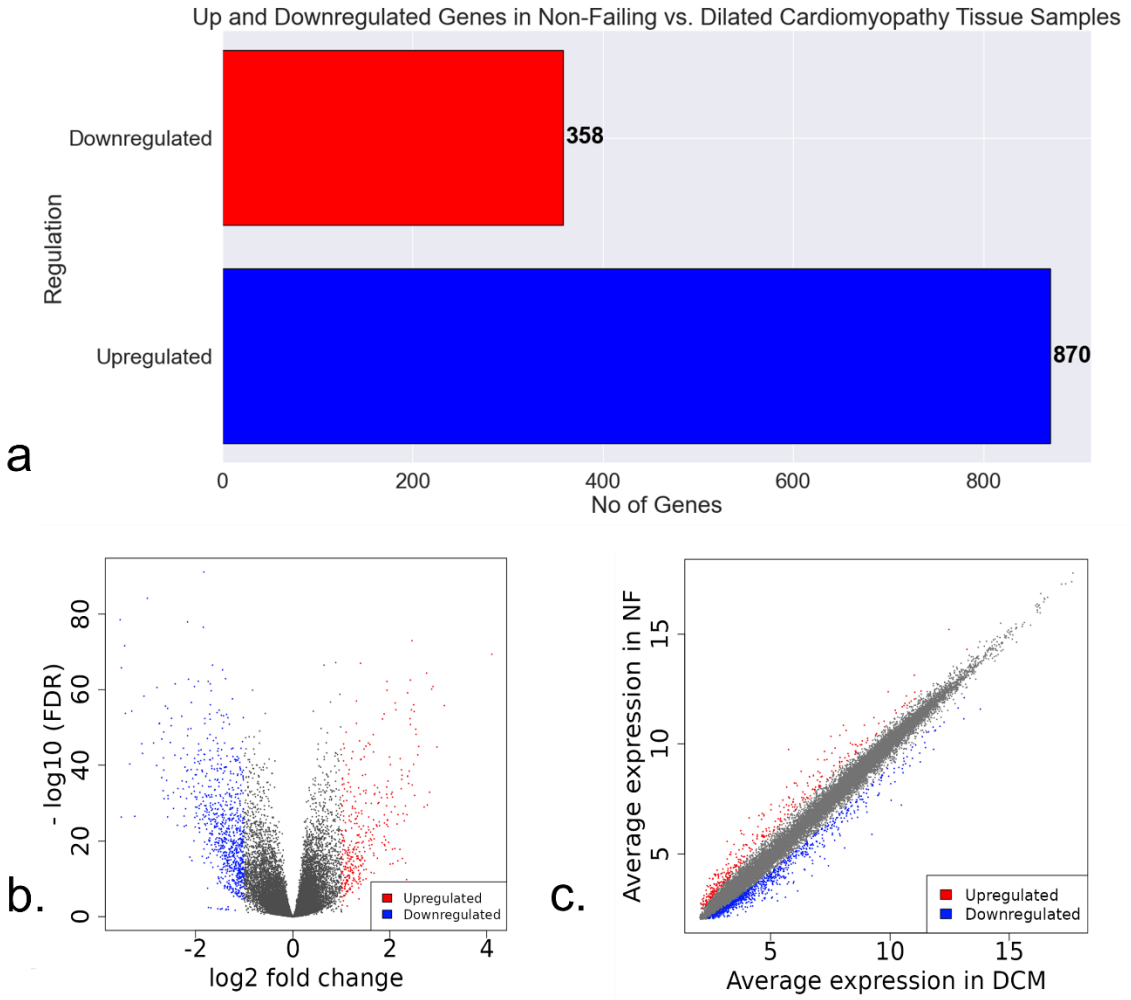

Figure 3.2. In the differential expression analysis between Non-Failing (NF) and Dilated Cardiomyopathy (DCM) tissue samples, we calculated the total number of differentially expressed genes using the limma-voom method. a. The total number of differentially expressed genes calculated using the limma-voom method. b. The Volcano plot shows the distribution of genes across different expression levels between NF and DCM samples. c. The Scatter plot demonstrates the total number of genes upregulated vs downregulated in Non-Failing and Dilated heart samples.

3.3.2 Gene Enrichment Pathways in Differentially Expressed Genes

Enrichment analysis using the Gene Ontology (GO) process has revealed that significantly downregulated genes are prominently enriched (indicated by low adjusted p-values) in pathways associated with extracellular matrix and structural organization, external encapsulating structure organization, immune response, and cell exterior organization. Conversely, upregulated genes are predominantly enriched in pathways related to immune response activation. Furthermore, we have individually identified the top upregulated and downregulated genes. Additionally, we observed that certain cell signaling pathway modules were upregulated in our analysis.

Table 3.1. Enriched pathways and the number of significantly up and down regulate genes in those pathways.

Direction	Adjusted P-values	No of the Genes	Pathways that have these genes
Down regulated	8.8e-17	58	Extracellular matrix organization

	8.6e-03	3	Negative regulation of fibrinolysis
	8.6e-03	19	Cellular divalent inorganic cation homeostasis

In addition to identifying the pathways enriched by the differentially expressed genes, we have listed the top genes in Table 3.2. Most of the genes presented in the table are protein-coding genes. Additionally, there are several long non-coding RNAs (lncRNAs) among the pool of differentially expressed genes. Both genes and lncRNAs are listed based on their corresponding p-values, with those having the largest p-values shown.

Table 3.2. Top genes that are differentially expressed in non-failing vs the dilated cardio-myopathy tissue samples.

3.3.3 Overlapping relationships among enriched gene-sets

We presented a network that illustrates the overlapping number of genes in enriched pathways. This network reveals a significant number of genes shared by different pathways in DCM samples.

3.3.4 Identification of Transcription factors that are import for fibrosis

We used an extremely stringent filtering process to identify the 23 transcription factors (TFs) for the context of our study. Using the GRnBoost2 algorithm we first ended up getting almost 2 million interactions. Initial filtering with CHIPX and TRANSFAC reduces the total no TFs- target interactions (Edges) to ~ 360,000. Fibrosis related filtering then reduces the number of edges to around 1300. In our final step, we used an important score >3 and only selected TFs that are only present in at least 8 out of 10 grids of network training. List of the TFs are presented in table 3.3 below.

Figure 3.3. The relationship between two pathways using WGCNA analysis. Here we used a 10% edge cutoff to allow connection between two pathways when there is 10% similarity.

Table 3.3. List of transcription factors derived from MAGNet Study. These transcription factors are connected to 178 edges with an importance score of greater than 3 and present in at least 8 out of 10 training datasets.

Transcription Factors	BCL6, CACYBP, CEBPD, CUX1, EGR1, ETS1, ETS2, HIF1A, LEF1, IKZF1, KLF4, MITF, NR5A2, PPARA, RARG, RUNX1, RELA, TEAD4, RUNX2, TCF4, TFCP2L1, WT1, ZNF281

3.4 Discussion

Cardiac fibrosis is a major pathophysiological manifestation of various heart diseases and can be simply defined as the excessive accumulation of the heart's extracellular matrix. As a pathological manifestation, patients may experience changes in the electrophysiological conduction of the heart. As defined, this process is very complex and involves several pathways and biochemical markers, such as the Matrix Metalloproteases (MMPs) and their tissue Inhibitors (TIMPS), renin-angiotensin-aldosterone system (RAAS), Transformation Growth Factor Beta (TGFβ) pathway, inflammatory mediators (IL1, IL6, and TNFα), and a multitude of long noncoding RNAs (lncRNAs) [21, 22]. Moreover, recent studies have also shown that male-female sex differences result in varying manifestations of cardiac fibrosis [23]. Overall, the process of cardiac fibrosis, though it may seem well-defined, requires further study to validate new target biomarkers for treatment.

Dilated cardiomyopathy is the most prevalent form of cardiomyopathy among the elderly. Surprisingly, there are no large-scale studies that have investigated the pathogenicity, disease manifestation, clinical course of disease, survival analysis, and drug

target discovery using genomic data for dilated cardiomyopathy. The purpose of the MAG-Net study is to shed light on these aspects of cardiomyopathy. In the current study, we performed bioinformatics analysis to identify the differentially expressed genes and enriched pathways that play an important role in dilated cardiomyopathies. Though further experimental validation is required, this study can serve as a primer for further validation of biomarker discovery.

After analyzing 332 patient tissue samples, the bioinformatics analysis revealed 359 downregulated and 870 upregulated proteins in DCM tissue samples compared to the NF patients. Subsequently, we conducted enrichment analysis and employed Whole Genome Co-expression network analysis to study potentially enriched pathways and build a network among them. From this study, we identified 23 unique transcription factors, which we validated using existing literature. This network was used for building the network for aim 3. Our differential expression analysis included both protein-coding genes and numerous long non-coding RNAs (lncRNAs). While lncRNAs play essential roles in post-translational gene modification and self-coding [22], our focus in this study solely centered on the cell signaling pathways of proteins, and therefore, we did not include the long non-coding RNAs in this analysis.

Among the differentially expressed genes, several genes seem very important in the context of fibrosis. The most differentially expressed gene was the Interleukin receptor type 1 gene (IL1RL1), responsible for binding and releasing IL-1α from damaged cardiomyocytes in the early stage of cardiac remodeling [24]. Downregulated in DCM patients were the Hemoglobin Subunit Alpha (HBA1 & HBA2) genes, which has a significant role in hypertension [25]. The gene SFRP4 plays a major role in the progression of myocardial ischemia [26], while Proenkephalin (PENK) along with IL1RL1 [27], is also differentially

expressed in Heart Failure patients. The MYH6 gene is strongly associated with hypertrophic cardiomyopathy according to some studies. Additionally, we identified two differentially expressed collagen genes (COL22A1 & COL10A1) [28, 29]. The COL22A1 gene encodes a protein found in the myotendinous junction of the heart, skin, and tendons, and its knockdown causes muscular dystrophy in animal models. On the other hand, COL10A1 serves as a biomarker for tumors in prostate cancer. Tubulin alpha genes (TUBA3A, TUBA3D, TUBA3E) are also upregulated in dilated cardiomyopathy patients [30]. Regarding the pathways most affected in dilated cardiomyopathy, ECM organization pathways were the most impacted, followed by immune response, biological adhesion, and matrix migration pathways. Conversely, acute phase inflammatory responses were the most upregulated responses in cardiac fibrosis.

Among the 23 derived transcription factors, some of them have unique implications in cardiac fibrosis. For instance, Bcl6 has been identified as an important transcription factor that suppresses cardiac fibroblast activation and function by directly binding to Smad4 [31]. EGR1, on the other hand, is involved in regulating cell growth, differentiation, and the response to stress and injury, making it crucial to understand its role in fibrosis [32]. Additionally, HIF1A, a master regulator of transcription, plays an important role in cellular responses to low oxygen levels [33]. Finally, ZNF281, another major player in fibrosis [34] has been discovered to be a significant transcription factor in our dataset.

3.5 Conclusion

Though this differential expression and functional enrichment analysis shed light on the crucial players of DCM, further validation is necessary to confirm them as potential biomarkers. Cell culture and animal model studies are needed to establish their role as

viable biomarkers for diagnosis or drug targets. Nevertheless, this study has identified several upregulated and downregulated genes that can serve as a starting point for further investigation. In addition, we identified important transcription factors that can be used in our aim 3 to build a GRN specific to Cardiac fibrosis. Utilizing these biomarkers also entails developing blood tests that can correlate with their expression levels, as obtaining left ventricle tissue samples poses ethical challenges.

Chapter 4

Building a Composite Gene Regulatory Fibroblast Network Model

4.1 Introduction

Cardiac fibrosis is a common manifestation of many cardiovascular diseases and can be defined as the excessive accumulation of extracellular matrix by cardiac fibroblasts [1]. Cardiac fibroblasts are similar to cells that produce connective tissue but are dissimilar to bones and tendons. In the heart, they build an extracellular matrix (ECM) that is dense, irregular, and composed of collagen, proteoglycans, and glycoproteins [2]. Cardiac fibrosis is the inherent response to any injury to the heart [3]. Cardiac fibroblasts produce a response to inflammation, proliferation of nonmyocytes, and scar mutation as a first line of defense. Later this response produces excess collagens and other extracellular matrix proteins. While the primary purpose of this protective mechanism is to maintain the integrity of the heart, long-time exposure results in the loss of the heart's contractile power [4]. Therefore, it is crucial to know the mechanistic regulation of cardiac fibrosis [6].

Cardiac fibrosis event consists of different pathways that include the neurohumoral pathway [7,8] such as the RAAS system, GPCR/Adrenergic signaling pathway, Endothelin -1 pathway, Fibrogenic Growth Pathway, TGFβ signaling pathway, Platelet Derived Growth Factor, Inflammatory Pathway such as the TNFα and IL6 pathways. Several biochemical molecule species from these pathways play an essential role in cardiac fibrosis. These molecules are from different pathways and are involved in the intricate cycle of cardiac fibrosis. These pathways crosslink with each other and crosstalk through cell signaling pathways. There are several modeling approaches for cardiac fibrosis primarily

falling into two broad groups: machine learning vs.mechanistic approaches. Each of these approaches has its strengths and limitations. Machine learning models are the most convenient approach for any domain nowadays due to the availability of many frameworks. However, they are limited in capturing biological processes, such as the input-output relation in cell signaling pathways. [9, 10]

Mechanistic models have been used for decades to understand the mechanism of disease and complex biological networks. These models are primarily dynamic and can be used to understand disease networks, drug response, and complex disease network analysis. However, the recent advancement of interpretable machine learning methods also seems promising for understanding the mechanistic approach of disease modeling. Mechanistic models have another significant limitation compared to machine learning approaches. It is tough to incorporate data from different sources in mechanistic models. However, mechanistic models are most usable when we have a small dataset and a single data type. It is sometimes tough to obtain large datasets for machine learning for studies like MAGNet [11] and SMART-AV clinical trials [12]. In those cases, mechanistic models are more accurate in qualitative prediction of the model output because of their deterministic nature.

Understanding the dynamics of large network models requires a complete understanding of the network and its parameters [13, 14]. As more parameters get involved, the model becomes complex and requires more experimentally measured parameter data to validate those models. Some of these chemical reactions are very prompt, and measurement of individual reactions is not feasible. Measurement of such parameters is problematic if multiple crosstalk is involved in the network. Parameter optimization and parameter exploration are easy for small biochemical networks but difficult for more extensive

networks. For larger systems without knowledge about the parameters, logic-based systems can provide significant mechanistic insight into any model. The advantage of these models is that they can keep the network's magnitude but provide qualitative insight into the model by setting a logical relation among the network species. Reactions in which one species activates/inhibits another species, along with another species, can be defined using logical AND, OR, and NOT gates [15]. Since biological reactions are limited to a few basic types of reactions (translation, transcription, and replications), we can set basic parameters related to concentration and time and validate models only using those parameters.

The Myocardial Applied Genomic Network (MAGNet) is a large-scale clinical study to collect cardiac tissues [18]. Dilated cardiomyopathy (DCM) tissue samples were collected from patients undergoing heart transplants. On the other hand, healthy heart donor tissues are Non-Failing (NF) tissue samples collected from the left ventricle-free walls and processed for the RNAseq data for different downstream analyses. MAGNet is one of the most significant studies to compare to study the genomic landscape of the DCM.

In this chapter, we used the gene regulatory network inferred from Chapter 3 to build a composite gene regulatory network. We integrated the previously built cardiac fibrosis network into our study. We simulated the model to predict the qualitative change in the pro-fibrotic molecules. In addition, we will do the perturbation analysis to study the most critical nodes in our model. Finally, we will conduct a patient-specific simulation to identify the most relevant clinical variables in the MAGNet.

4.2 Methods

4.2.1 Building a composite gene regulatory network for NF and DCM patients

The previously published signaling network model for cardiac fibrosis relied on a manual literature search [19, 20]. They used more than 300 articles to build the cardiac fibrosis network. This network has expanded using a gene regulatory network derived from different GRN inference algorithms. The Rogers et al. study [21] presented a way to incorporate the gene regulatory network into the network. In our study, we have followed a similar approach for DCM patients. We build the gene regulatory network using the GRNBoost2 [22] algorithm by the approach used by the authors.GRNBoost2 algorithm is a regression-based method to predict the regulatory link between the input and the target gene. The famous Gene Network Inference with Ensemble of Trees (GENIE3) algorithm works in the base GRNBoost2 method. The GENIE3 algorithm performs well in all benchmarking analyses and is consistently a top performer in inferring gene regulatory interactions. In GENEI3, ensemble trees predict the expression of a given target gene from the expression of all other genes. This algorithm is better than other gene regulatory network inference algorithms. For example, it does not require understanding network topology and can infer directed interactions by comparing the correlation and probability-based methods. Moreover, this algorithm can infer nonlinear regulations as well. For our study, we used a different approach to pruning the inferred GRN. The initially inferred network has thousands of non-specific interactions unrelated to fibrosis. Multi-step network pruning removes these non-specific interactions. First, we only allowed the literature-supported transcription factor target interactions. We used the Chromatin Immune Precipitation (CHIP-X) and Transcription Factor (TRANSFAC) database to cover the maximum number of transcription factors with experimental evidence. Upon filtering for the transcription

factors, we again filtered out the network that is only related to the output of the fibroblast mechanotransduction network. We also added genes (MYH6, COL22A1, COL10A1) significantly different between nonfailing vs. dilated cardiomyopathy tissue samples. Finally, we used a depth-first search (DFS) algorithm to prune the network edges. This algorithm helps us to identify possible pathways between each primary transcription factor and target and check whether each interaction meets the required importance score. Only highly ranked interactions are allowed here. Interactions are only allowed if the importance score of each edge is higher than the 90th percentile. These filtering steps help to reduce the noises by non-specific interactions. Since our dataset has a lot of replicates, we, trained the network model by dividing the dataset into ten folds. We only selected the edges derived from network inference , pruning, and, present in at least 8/10 fold of data. Finally, we filtered the gene regulatory network using literature/articles that validate the presence of those TF in at least one article.

4.2.2 Building the Logic Based ODE model.

We integrated this transcription factor and target network into the cardiac fibroblast mechanotransduction network, a logic-based ODE model. This model is logic-based because the approach allows logical interaction between the biochemical species/model components. For any cell signaling species x, the activation and inhibition can be modeled as a Normalized Hill Equation [23] as –

$$fact(x) = \frac{Bx^n}{k^n + x^n}$$

$$finhib(x) = 1 - \frac{Bx^n}{k^n + x^n}$$

Here n is the Hill coefficient related to the gradient of the activation or inhibition dose-response. The constant B and K are additional constants characterizing the dose-response curves and can be expressed as -

$$B = \frac{EC_{50}^{n} - 1}{2EC_{50}^{n} - 1}$$

$$k = (B - 1)^{\frac{1}{n}}$$

Where EC_{50} is the value of x when half maximum activation occurs. The primary logics here are 'AND', 'OR', 'ANDNOT' involved in two types of reaction (activation/inhibition). If two biochemical species involved in an activation/inhibition reaction, the equations can be written as -

$$xANDy = fact(x) * fact(y)$$

$$xORy = fact(x) + fact(y) - fact(x) * fact(y)$$

$$xANDNOTy = fact(x)(1 - fact(y))$$

Complex logical reactions can be used for complex reactions involving 2 or 3 species. As we can see these reactions are only dependent on the reactants not the product. In addition to these n and EC_{50}, which are specific to any specific biochemical reactions, another parameter Reaction Weight (w) can be used to better for the quantitative experiments. Besides these three reaction parameters, there are three different species/node specific parameters. Each node has a decay timescale tau (τ) and a maximal activity level, ymax $\in$ [0,1]. For any reaction an ymax value of 1 is used by default. We can use a different value if we want to lower the maximum activation level of any node (between 0 and 1) or knockdown of any node (ymax = 0). In our model we have set specific value for these

parameters. We set the initial activation level y0 = 0 for all species, τ is set to 1, 0.1, 10 based on the type of reaction. For translation it is set to 0.1, 1, 10 based on the type of translation reactions. On the other hand, τ for all GRN transcription reactions are set to 1. We used normalized RNASeq data between 0 and 1, and set that as ymax values. For our model we used ymax value for all the input reactions as w, all internal and output reaction weights are set to 1, n is set to 1.4, EC_{50} set to 0.6. These logics are implemented into a dynamical model where change of each species is integrated into the differential equations presented in the supplemental table S4.1 & S4.2. The implementation of these models is done in MATLAB package Netflux [23]. The model was created using Cytoscape and PowerPoint.

4.2.3 Model Validation

In all previous studies, the network validation steps consist of literature validation. However, for this current study, we have the RNASeq dataset to compare the input-output relation in the dataset. We normalized the RNAseq data to compare the NF and DCM tissue samples. To do that validation, we have normalized the SVA samples. We exclude the outliers in each gene. To do that, we excluded the data that spread between 10-90% of the data. We have excluded the dataset above these spreads and replaced them with the top 90 or 10% percentile data points. Then each gene expression data was normalized between 0-1. Since we removed the data's outliers, we included a change in gene expressions at a minimum of 1%. Since this is our logical model, we compared the qualitative outcome of the model rather than the numerical aspect of the model. We compare the model output in response to the input values as RNASeq. The output of the model compared with the bulk RNAseq data. These differences have three categories increase, decrease, and no change. Instead of predicting like machine learning algorithms, this model

represents the mechanical aspects of cardiac fibrosis. The matching and mismatching model predictions are presented as a matrix in Figure 4.2. All the simulation data were generated in MATLAB, and all the graphs were prepared using the Python package Matplotlib.

4.2.4 Network Perturbation Analysis

Network perturbation analysis was conducted to identify the influential signaling node in the DCM tissue samples. First, the model was simulated using the baseline parameter values. To do that we first set the ymax for each node from normalized RNAseq data then set the ymax of all the nodes to 10% of the set ymax. We then also set all the input reaction weights (w) equivalent to the baseline ymax value. We ran the simulation using this baseline values and saved as. Then, we simulated the model using the ymax and input weight value derived from RNASeq. We recorded the change of value as Δ(Activity). The changes are plotted in a heatmap in Figure 4.3.

4.2.5 Correlation between Model Predicted output clinical variables.

We also used the patient's clinical and demographic variables, such as age, weight, height, heart weight, left ventricular mass, and left ventricular ejection fraction (LVEF), to find a correlation with the model-predicted outputs. To do that, we first simulated the model for all patients. We measured the output of the model. We then filtered the data that has all clinical variables present. We then used Pearson correlation coefficient for this. This correlation matrix is presented in Figure 4.4.

4.3. Results

4.3.1 Integration of gene regulatory network to the fibroblast signaling network

After inferring the gene regulatory network using the GRNBoost2 algorithm, we found around 1300 unique edges. These edges are further filtered for the nodes that are connected to either the list of transcription factors or connected to the output of the mechanistic pathway of the cardiac fibrosis model. All these final edges were again validated with the literature supporting the interaction. Moreover, we had to add connection reactions to the intermediates to the network. This results in total addition of 142 more edges.

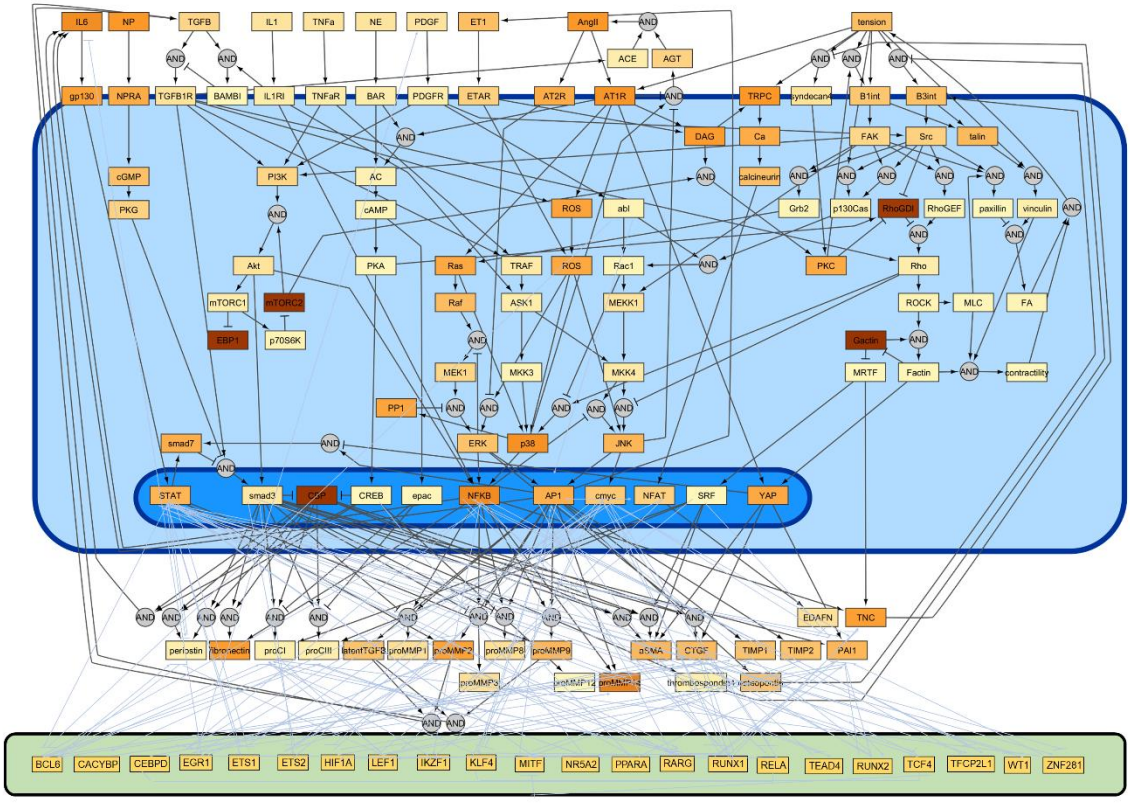

Figure 4.1. The combined gene regulatory network. The model consists of two parts. The

top one is adopted from the previous fibroblast mechanotransduction network. The bottom green part is inferred from the MAGNet gene regulatory network.

4.3.2 Model Accuracy after integration of the gene regulatory network

To validate whether the model still shows the same performance as the original fibroblast mechanotransduction model [20]. We have added 142 more edges and made the model show a similar level of accuracy. The final accuracy of the model was relatively the same after adding those edges to the model (Figure 4.2). The simulations ran for only 100 sec to validate the expression change in the input, intermediates, and output of the model.

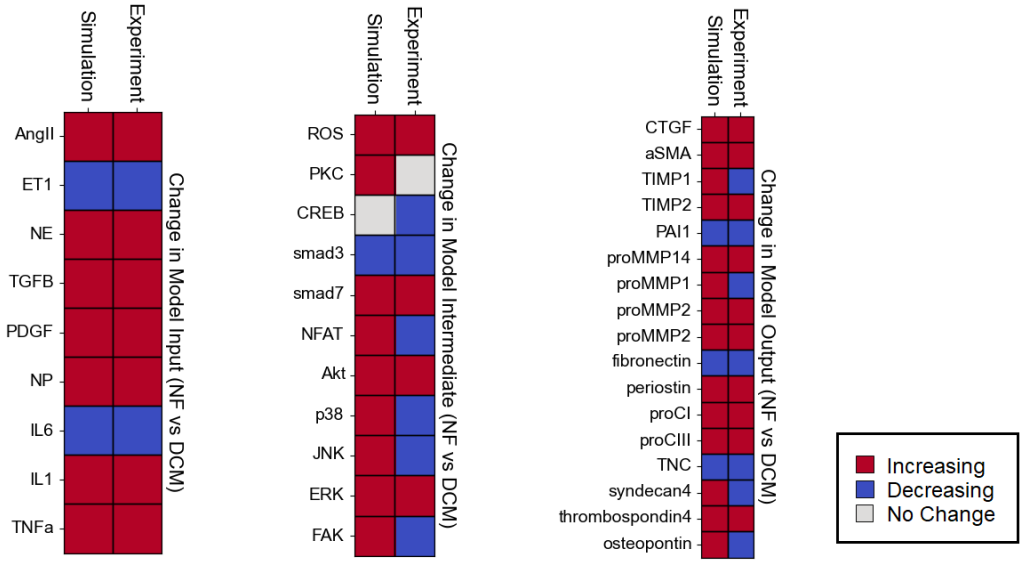

Figure 4.2. Validation of the composite model. Addition of the Gene Regulatory Network did not change the accuracy of the model compared to the previously reported models. The model showed better performance in predicting the qualitative changes in Non Failing to Dilated Cardiomyopathy tissue samples.

4.3.3 Perturbation analysis identifies important network drivers

Perturbation analysis showed the most important nodes in our model. Tension is the most important factor here. Its knockdown showed the single most effect in the network. The second most effected node is the activator protein (AP1) which regulates gene expression in the presence of various stimuli, such as stress/mechanical tension, cytokines, growth factors, and infections [24]. The third most perturbed node is the Nuclear factor kappa-light-chain-enhancer of activated B cells (NFKB) is the third most perturbed node. During cardiac remodeling, NFKB exerts cytotoxic effect by prolonging inflammatory response, which is a hallmark of cardiac fibrosis. Early growth response 1 (EGR1) is the only transcription factor that can be included in the top perturbed node [25, 26]. This transcription factor is activated with the onset of cardiac hypertrophy in the left ventricle of the heart. Among the receptors, Angiotensin II type 1 receptor (AT1R) is the most perturbed. Angiotensin II activates mechanotransduction through the receptor AT1R, increases the intracellular Ca^{2+} concentration and promotes hypertrophic cardiac remodeling [27]. Nuclear Factor of Activated T-cells (NFAT) is also perturbed to the highest degree [28].

4.3.4 Correlation among clinical variables and model outputs

Correlation analysis showed the relationship between cardiac function variables Left Ventricular Mass (LV_Mass), Heart Weight, and Left Ventricular Ejection Fraction (LVEF). There is no strong correlation found in this correlation analysis except for the Tissue Inhibitors for Metalloprotease 2 (TIMP2).

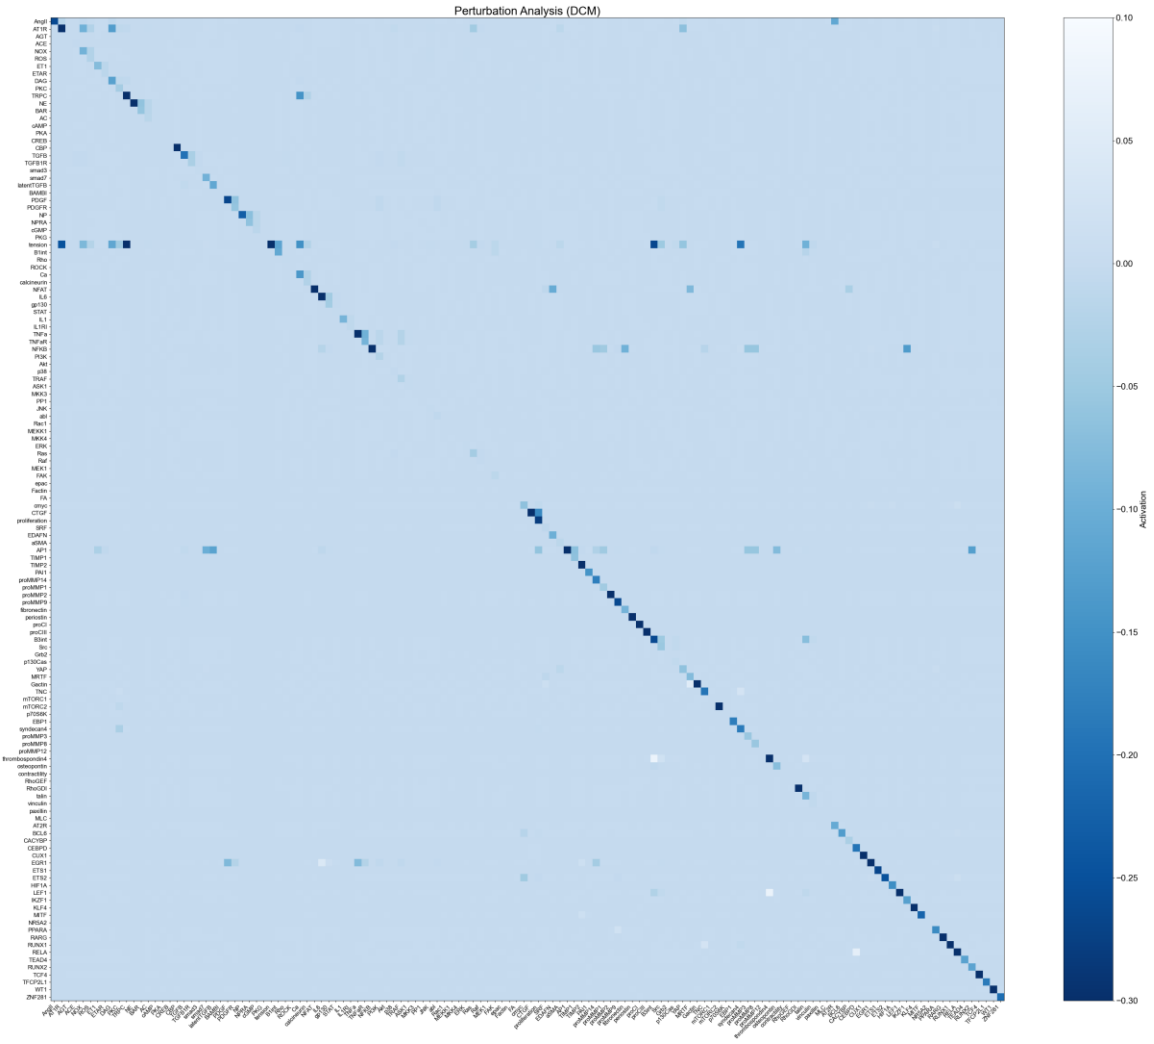

Figure 4.3. Perturbation analysis showed the most important nodes in the network. We simulated the model with baseline ymax values (0.2) for each of the nodes.

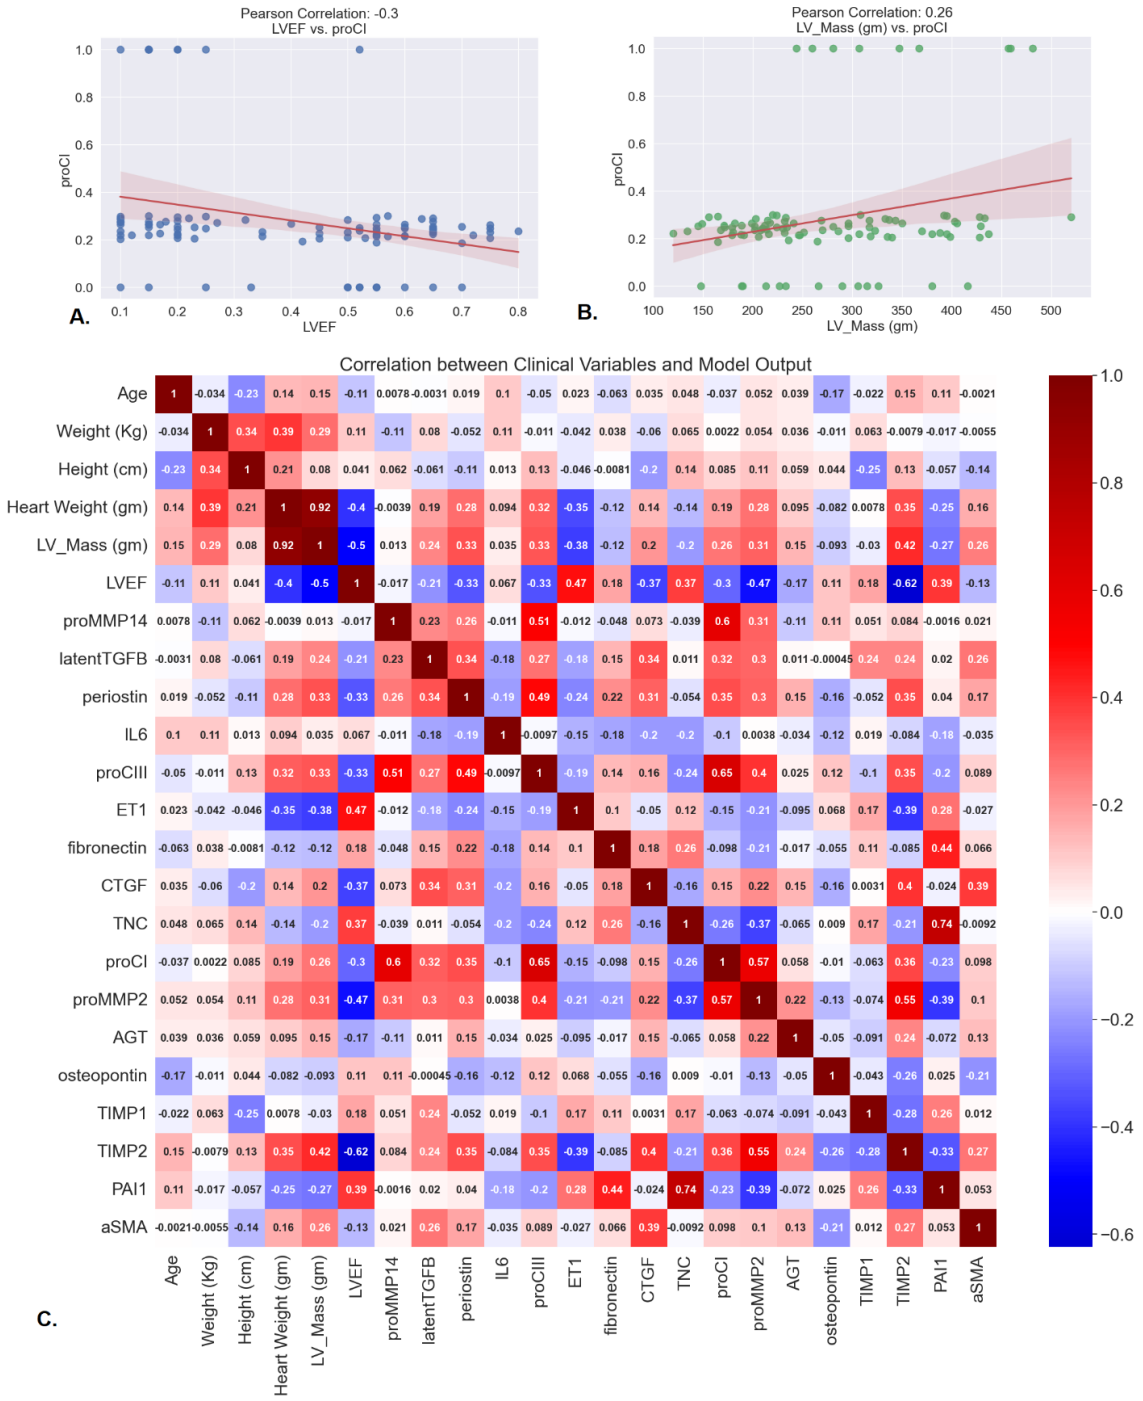

Figure 4.5. Pearson correlation among the model predicted output and clinical variables. We ran the simulation for each patients who has complete clinical variables. A. Correlation between simulated proCI and Left Ventricular Ejection Fraction (LVEF). B. Correlation

between simulated proCI and Left Ventricular Mass. C. Correlation among the outputs and numerical measurements. All of these simulated data have some outliers values due to reaching into steady state or not expressing the fibrotic outputs.

4.4 Discussion

Cardiac fibrosis is a complex disease that involves crosslinking multiple pathways from cell development and growth to immune responses. Developing a proper therapeutic target requires a complete understanding of the complex network. Gene regulatory networks, though insufficient to elucidate the intracellular dynamics, play an essential role in how cellular effectors interact. Therefore disease-specific gene regulatory networks are essential to infer and integrate into the mechanistic model of cardiac fibrosis. With the availability and ease of machine learning algorithms, modelers are more prone to machine learning models. However, with a limited amount of patient-specific data and a large number of variables, it is more rational to use mechanistic models instead of machine learning to understand diseases. Mechanistic models are more accurate and applicable to patient-specific modeling [29].

In this chapter, we integrated fibrosis related gene regulatory networks into our model. Upon comparing them with the experimental data, we found the most similarities in output nodes, followed by the input and intermediate nodes. The accuracy in predicting the qualitative change in output is very encouraging (77%) which is almost similar to the original fibroblast models.This is interesting since we did not fit it to experimental data, rather used them as input. This also validate that gene expression does not equate protein expression in intracellular signalling models. Therefore, further proteomics study needs to validate the qualitative output change of the model [30].

The perturbation study analysis uncovered tension as the most influential node in the DCM patient. Tension is the mechanical stimulant for left ventricular hypertrophy. The heart must work hard to counteract tension and maintain its pumping capability. This results in the thickening of the heart , which is responsible for pumping oxygen-rich blood to the organs. Therefore, tension is the most critical node in our model. In cardiac diseases, AP1, NFKB, and EGR1 are important intermediates crosslinking different pathways, resulting in left ventricular hypertrophy development. Due to mechanical stress, several kinase pathways get activated and activate NFKB, AP1, and EGR1. Activation of these crosslinking molecules, a cascade of transcriptional programming starts and induce the transcription of Platelet-Derived Growth Factors (PDGFs), Transforming Growth Factors (TGFs), tissue factors, matrix metalloproteinases (MMPs), and collagens (such as COL1, COL3) [25-27,31]. These start a cascade of physiological changes such as atherosclerosis, angiogenesis, ischemic disease, and cardiac hypertrophy. All of these are potential triggers for cardiac remodeling. The Angiotensin II receptor ATR1 plays a vital role in cardiac hypertrophy. Its activation results in the activation of the TGFβ1 pathway through its receptor. The activation of TGFβ1 activates Extracellular Signal-Regulated Kinase 1 and 2 (ERK1 and 2) pathways. Phosphorylated ERK1/ERK2 stimulate overexpression of growth factors and neurohormonal mediators. All these lead to left ventricular hypertrophy [32].

Though we did patient-specific simulations to show the relation between clinical variables and model outputs, we did not find a strong correlation. This is somewhat expected because of the lack of different data types. In our study, we have used RNASeq data as model input as well as to validate the model. But the correlation between mRNA/RNASeq and protein is not straightly correlated. This is due to the different half-life

for different transcript and protein, post transcriptional modifications of the mRNA transcripts [30]. Therefore, we need a proteomic data set to fit and train the model for more accurate qualitative prediction of the change in model intermediates and outputs. Another factor that is strongly contributing to this low correlation is the outlier data derived from the simulation. This is because we have a small panel of complete patient data. After imputing, we ended up getting only 99/332 patients who has complete set of clinical data. Extensive studies should be conducted on such relations to find relations among pro-fibrotic outputs and cardiac function variables.

4.5 Conclusion

In this chapter we integrated the gene regulatory network derived from the previous chapter into previously built fibroblast mechanotransduction network. These combined mechanistic models showed very similar qualitative prediction of the mediators of fibrosis, especially in terms of predicting the qualitative change in input. Further analysis of the clinical variables has shown how they correlate with the model outputs. Due to ethical issues, it is very hard to obtain real tissue samples from actively pumping hearts left ventricles. MAGNet study has given us the opportunity to compare the dynamics of transcriptomics between the Non Failing donor heart and Dilated Cardiomyopathy patients. We leveraged this opportunity to build a logic based model. Future direction of this study will be building a most robust model by integrating an efficient parameter estimation method and adding a drug perturbation study.

Chapter 5

Conclusion, Limitation, and Future Direction

5.1 Summary of Findings

In this dissertation, we utilized interpretable mechanistic and machine learning models to predict cardiac remodeling based on biochemical and biomechanical features. Aim 1 demonstrated the effectiveness of integrating multiple data types, such as demographics, comorbidities, therapy history, circulating biomarker levels, and echo-based left ventricular function data. This integration significantly improved the predictive capability of our machine learning algorithms in identifying responders and non-responders to cardiac resynchronization therapy (CRT). By leveraging this diverse set of features, we achieved an identification rate of 71% for patient response, with an area under the curve (AUC) of 0.784. In Aim 2, we focused on identifying differentially expressed genes upregulated in the non-failing (NF) versus dilated cardiomyopathy (DCM) left ventricle tissue samples obtained from donors and recipients. We employed a gene regulatory network inference algorithm called GRNBoost2 to achieve this and incorporated these identified genes into the analysis. We identified 23 unique transcription factors connected to 17 profibrotic biochemical species and other cellular intermediates through a novel multistep filtering algorithm. These connections represent 158 activation/inhibition reactions (edges). Aim 3 integrated the 158 GRN edges into an existing logic-based ordinary differential equation (ODE) model to predict the qualitative changes in model input, intermediate, and output components. Our model demonstrated comparable predictive capability to the

previously established fibroblast mechanistic network. Furthermore, we conducted patient-specific simulations to illustrate the relevance of clinical variables in our findings.

Overall, our research contributes to a better understanding of cardiac remodeling prediction by applying both interpretable mechanistic models and machine learning algorithms. By combining various data types and integrating gene regulatory networks, we have gained valuable insights into identifying responders to CRT and analyzing key transcriptional factors involved in cardiac remodeling. These findings have significant implications for advancing personalized cardiac disease treatment and management approaches.

5.2 Study limitations

Our aims in this study have certain limitations stemming from the nature of the research and the data availability. Firstly, the SMART-AV clinical trial data used in Aim 1 had a relatively short follow-up period of only six months for the patients. This limited timeframe prevented us from conducting a comprehensive survival analysis of the patients. It would have been valuable to have access to long-term follow-up studies [1] as well, as they could have aided in identifying patient-specific variables that contribute to long-term survival analysis. In Aim 2, we employed the GRNBoost2 algorithm to identify crucial interactions between transcription factors and biochemical species. However, to further refine the gene regulatory network, conducting a perturbation analysis to identify upstream regulatory signaling pathways from downstream gene expression (GEX) would have been beneficial [2].

Additionally, exploring patient-specific gene regulatory networks could have provided more profound insights into individual variations. For the final aim, we utilized the GRN network obtained from Aim 2 and used RNASeq data to fit both the input and output of the mechanistic model. Since our model comprises multiple parameters (y0, ymax, tau, w, n, and EC50), employing a parameter optimization method could have significantly enhanced the accuracy of model predictions. Some studies have successfully employed parameter optimization methods, such as nonlinear programming [3], genetic algorithms [4], and uncertainty quantification [5], to refine their models. Furthermore, it would have been valuable to modify the original fibroblast mechanistic model by adding or removing nodes not pertinent to dilated cardiomyopathy. This refinement could have resulted in more patient-specific and disease-specific mechanistic models.

In conclusion, while our research has contributed valuable insights into cardiac remodeling, it is essential to acknowledge these limitations. The short follow-up period of the clinical trial data, the need for further analyses in the gene regulatory network, and the potential for parameter optimization in the final model could be addressed in future studies to enhance our findings' robustness and applicability.

5.3 Future Direction

The limitations encountered in our aims have provided valuable opportunities for future research. In the first aim, further biochemical exploration of CRT patients can complement our machine learning models. By incorporating mechanistic models alongside machine learning, we could gain deeper insights into the input-output relationships through an extended study. Such an exploration would offer mechanistic insights into the effects of CRT treatment on patients, such as changes in pressure and volume in the left ventricle.

Understanding these aspects could enhance our comprehension of CRT treatment outcomes. We can extend the study for the second and third aims by incorporating additional data types beyond RNASeq data. Integrating proteomic studies would add another layer of information and potentially lead to more comprehensive findings. Moreover, implementing an efficient parameter estimation method would refine our models and improve the accuracy of predictions.

Expanding the scope of this study to include different types of cardiomyopathies, such as Dilated, Hypertrophic, and Peripartum, in patients would be worthwhile. Before extending to such studies, constructing a mechanistic network specific to cardiomyopathies would be paramount. The overarching goal of this study is to build interpretable models for cardiac remodeling using either machine learning or mechanistic modeling, both of which have their strengths and limitations. By combining these approaches, we have the potential to uncover new insights and enrich our current knowledge base. This integration may lead to more accurate and comprehensive models, ultimately advancing our understanding of cardiac remodeling and its associated complexities.

In conclusion, the limitations encountered in our study present exciting possibilities for future research. By exploring additional biochemical factors, employing mechanistic modeling alongside machine learning, integrating diverse data types, and extending the study to include different cardiomyopathies, we can advance our understanding of cardiac remodeling and pave the way for improved therapeutic approaches in cardiac mechanobiology.

Table S4.2 Species and Species parameters used in Chapter 4.

Species information							
module	ID	name	Yinit	Ymax	tau	type	gene name

g-coupled	AngII	angiotensin II	0	0.45	1	protein	AGT
g-coupled	AT1R	angiotensin II receptor type 1	0	0.49	0.1	protein	AGTR1
g-coupled	AGT	angiotensinogen	0	0.45	10	protein	AGT
g-coupled	ACE	angiotensin converting enzyme	0	0.32	0.1	protein	ACE; ACE2
g-coupled	NOX	NAD(P)H oxidase	0	0.34	0.1	protein	NOX4; NOX5
g-coupled	ROS	reactive oxygen species	0	0.50	0.1	protein	
g-coupled	ET1	endothelin 1	0	0.43	1	protein	EDN1
g-coupled	ETAR	endothelin 1 receptor A	0	0.27	0.1	protein	EDNRA
g-coupled	DAG	diacyl-glycerol	0	0.50	0.1	small	
g-coupled	PKC	protein kinase C	0	0.41	0.1	protein	PRKCA; PRKCE;
pressure/stretch	TRPC	transient receptor potential canonical	0	0.41	0.1	protein	TRPC6;TRPC3
g-coupled	NE	norepinephrine	0	0.50	1	small	
g-coupled	BAR	beta adrenergic receptor 1 or 2	0	0.45	0.1	protein	ADRB1; ADRB2
g-coupled	AC	adenylate cyclase	0	0.42	0.1	protein	ADCY6
g-coupled	cAMP	cyclic adenosine monophosphate	0	0.50	0.1	small	
g-coupled	PKA	protein kinase A	0	0.46	0.1	protein	PRKACA
g-coupled	CREB	cAMP response-element binding protein	0	0.48	0.1	protein	CREB1; CREB3
g-coupled	CBP	CREB - binding protein	0	0.42	0.1	protein	CREBBP
growth factor	TGFB	transforming growth factor beta 1	0	0.37	1	protein	TGFB1
growth factor	TGFB1R	TGFB receptor	0	0.47	0.1	protein	TGFBR1; TGFBR2
growth factor	smad3	small mothers against decapentaplegic 2 and 3	0	0.45	0.1	protein	SMAD2; SMAD3
growth factor	smad7	small mothers against decapentaplegic 7	0	0.40	10	protein	SMAD7
growth factor	latentTGFB	TGFB1 with latent protein complex	0	0.37	10	protein	TGFB1
growth factor	BAMBI	BMP and activin bound inhibitor	0	0.32	0.1	protein	BAMBI
growth factor	PDGF	platelet derived growth factor	0	0.36	1	protein	PDGFA; PDGFB; PDGFD
growth factor	PDGFR	platelet derived growth factor receptor	0	0.50	0.1	protein	PDGFRA; PDGFRB
g-coupled	NP	natriuretic peptide	0	0.29	1	protein	NPPA; NPPB

g-coupled	NPRA	natriuretic peptide receptor	0	0.32	0.1	protein	NPR1; NPR2; NPR3
g-coupled	cGMP	cyclic guanosine monophosphate	0	0.60	0.1	small	
g-coupled	PKG	protein kinase G	0	0.49	0.1	protein	PRKG1
pressure/stretch	tension	stretch	0	0.25	1	process	
pressure/stretch	B1int	beta 1 integrin	0	0.42	0.1	protein	ITGB1
pressure/stretch	Rho	a Rho-dependent GTPase	0	0.50	0.1	protein	RHOA
pressure/stretch	ROCK	rho associated protein kinase	0	0.50	0.1	protein	ROCK1
pressure/stretch	Ca	calcium	0	0.50	0.1	small	
pressure/stretch	calcineurin	calcineurin	0	0.55	0.1	protein	PPP3CA; PPP3CB
pressure/stretch	NFAT	nuclear factor of activated T-cells	0	0.33	0.1	protein	NFATC1
cytokine	IL6	interleukin-6	0	0.42	1	protein	IL6
cytokine	gp130	IL-6 receptor complexed to gp130 for signal transduction	0	0.47	0.1	protein	IL6ST; IL6R
cytokine	STAT	signal transducers and activators of transcription 1 and 3	0	0.37	0.1	protein	STAT1; STAT3
cytokine	IL1	interleukin-1 alpha and beta	0	0.27	1	protein	IL1B; IL1A
cytokine	IL1RI	IL1 receptor type I	0	0.51	0.1	protein	IL1R1
cytokine	TNFa	tissue necrosis factor alpha	0	0.50	1	protein	TNF
cytokine	TNFaR	TNF alpha receptor	0	0.45	0.1	protein	TNFRSF1A ;TNFRSF1B
cytokine	NFKB	nuclear factor kappa-light-chain-enhancer of activated B cells	0	0.45	0.1	protein	NFKB1
cytokine	PI3K	phosphoinositide 3-kinase	0	0.47	0.1	protein	PIK3CA
cytokine	Akt	protein kinase B	0	0.44	0.1	protein	AKT1; AKT2; AKT3
MAPK	p38	a MAP kinase	0	0.52	0.1	protein	MAPK14
MAPK	TRAF	tnf receptor associated factor either 2/6	0	0.53	0.1	protein	TRAF6
MAPK	ASK1	apoptosis signal related kinase 1	0	0.49	0.1	protein	MAP3K5
MAPK	MKK3	mitogen activated protein kinase kinase	0	0.38	0.1	protein	MAP2K3

MAPK	PP1	protein phosphatase 1	0	0.55	0.1	protein	PPP1CA; PPP1CB; PPP1CC
MAPK	JNK	a MAP kinase	0	0.44	0.1	protein	MAPK8
MAPK	abl	abl tyrosine kinase	0	0.50	0.1	protein	ABL1; ABL2
MAPK	Rac1	a Rho-dependent GTPase	0	0.51	0.1	protein	RAC1
MAPK	MEKK1	a MAP3K associated with p38 and JNK	0	0.55	0.1	protein	MAP3K1
MAPK	MKK4	a MAP2K associated with p38 and JNK	0	0.54	0.1	protein	MAP2K4
MAPK	ERK	a MAP kinase	0	0.46	0.1	protein	MAPK1; MAPK3
MAPK	Ras	representing the family of GTPases	0	0.53	0.1	protein	KRAS
MAPK	Raf	family of raf protein ser-ine/threonine kinases	0	0.58	0.1	protein	RAF1
MAPK	MEK1	a MAP2K mainly specific to ERK	0	0.43	0.1	protein	MAP2K1
adhe-sion	FAK	focal adhesion kinase	0	0.34	0.1	protein	PTK2
g-cou-pled	epac	exchange protein activated by cAMP 1	0	0.53	0.1	protein	RAPGEF3
adhe-sion	Factin	polymerized actin	0	0.42	1		ACTG1
adhe-sion	FA	stabilization of focal adhe-sions	0	0.50	1	complex	
growth	cmyc	myc transcription factor	0	0.45	0.1	protein	MYC
ECM	CTGF	connective tissue growth factor	0	0.36	0.1	protein	CTGF
growth	prolifera-tion	proliferation	0	0.50	10	event	
adhe-sion	SRF	serum response factor	0	0.36	0.1	protein	SRF
